

32-BIT SINGLE-CHIP MICROPROCESSOR

FEATURES

- Fully static operation
- 32-bit data bus
- 32-bit address bus
- Coprocessor interface for instruction set extension
- High-level language compiler support
- Fast interrupt response for real-time applications
- Big and Little Endian operating modes
- Boundary Scan for device and system testing
- Low power consumption

DESCRIPTION

The VY86C060 microprocessor is based on the ARM™ processor core from Advanced RISC Machines, Ltd. The VY86C060 is a general-purpose 32-bit, single-chip microprocessor. The architecture is based on Reduced Instruction Set Computer (RISC) principles, and the instruction set and related decode mechanism are greatly simplified compared with microprogrammed Complex Instruction Set Computers (CISC). This simplification results in a high-instruction throughput and a real-time interrupt response from a small and cost-effective chip.

The instruction set comprises ten basic instruction types. Two of these make use of the on-chip arithmetic logic unit (ALU), barrel shifter and multiplier to perform high-speed operations on the data in a bank of 32-bit registers. Three instruction types control the transfer of

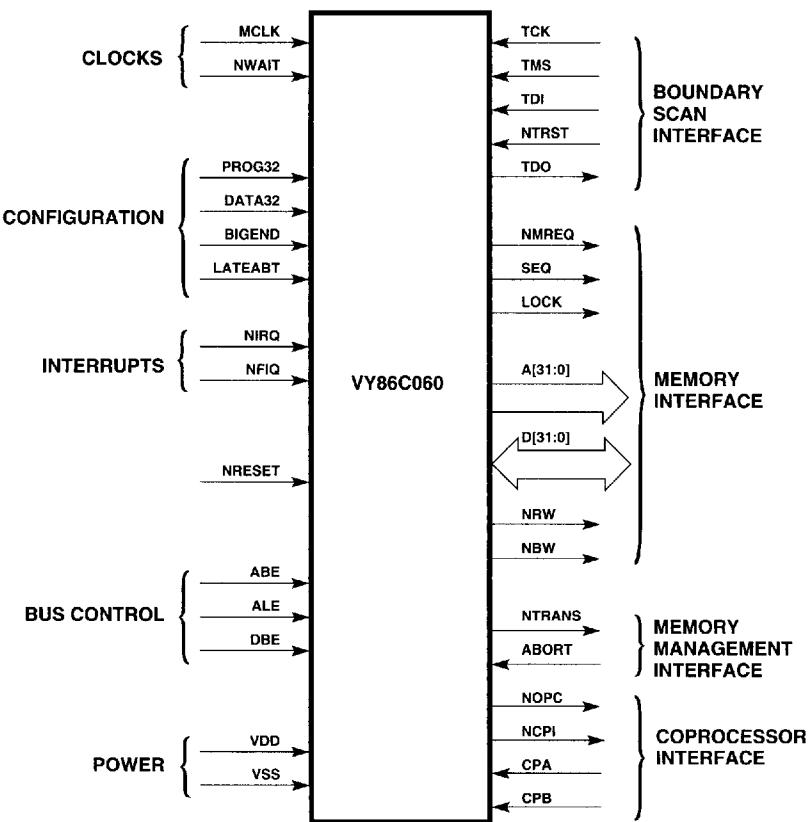

data between main memory and the register bank. One is optimized for flexibility of addressing, another for rapid context switching, and the third for indivisible semaphore operations. Two instructions control the flow and privilege level of execution, and the remaining three types are dedicated to the control of external coprocessors, which allow the functionality of the instruction set to be extended off-chip in an open and uniform way.

The VY86C060 instruction set has proved to be a good target for compilers of many different high-level languages. Where required for critical code segments, assembly code programming is also straightforward, unlike some RISC processors that depend on sophisticated compiler technology to manage complicated instruction interdependencies.

Pipelining is employed allowing for all parts of the processing and memory systems to operate continuously. Typically, while one instruction is being executed, its successor is being decoded, and a third instruction is being fetched from memory.

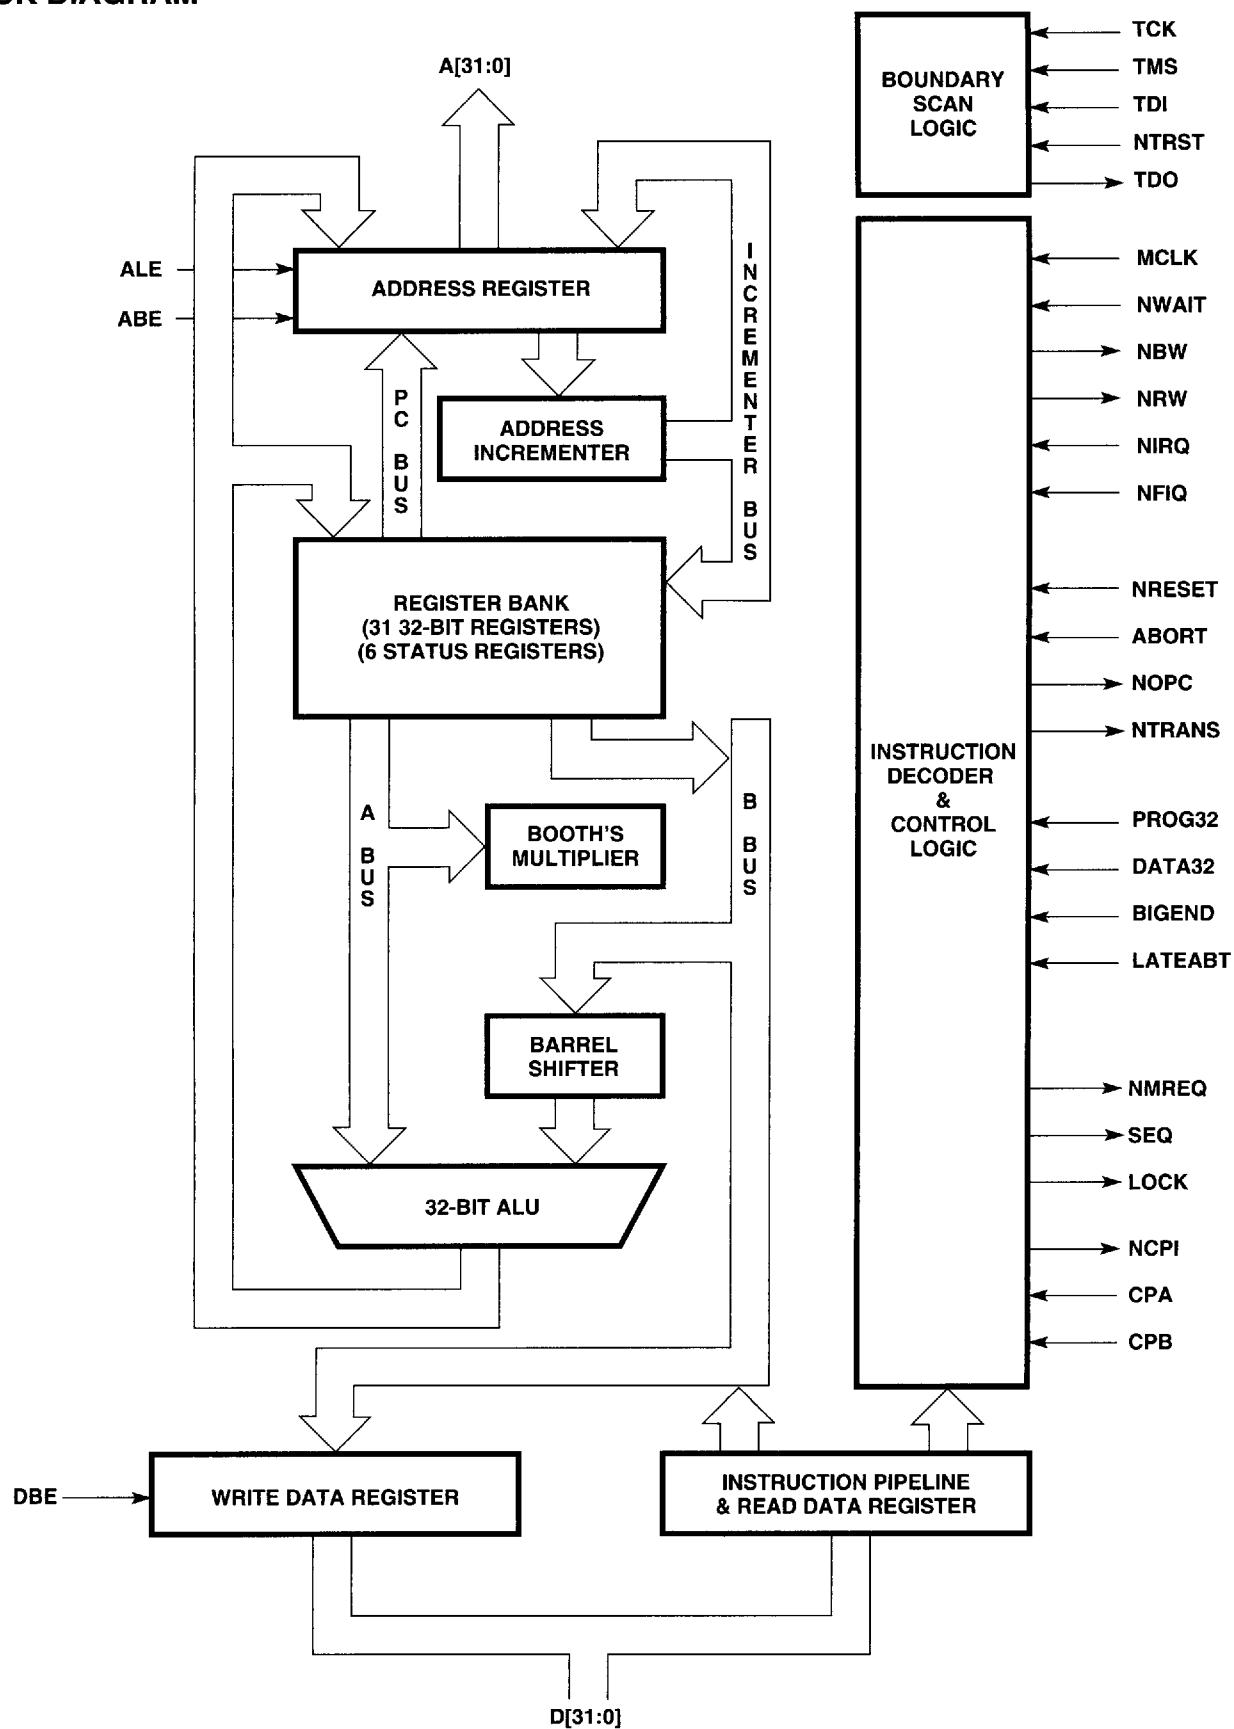

The VY86C060 is based on the VY86C006 FSB™ library element, and is software compatible with the instruction set of earlier ARM processors (ARM2, ARM2aS, and ARM3). Unlike these processors, which have a 26-bit address bus, the VY86C060 has a 32-bit address bus. For backwards compatibility, it can also be configured to use a 26-bit address bus. It is a fully static implementation that allows the clock to be stopped in any part of the cycle with minimal residual power consumption and no loss of state.

FUNCTIONAL DIAGRAM

BLOCK DIAGRAM

SIGNAL DESCRIPTIONS

Name	Type	Description
A[31:0]	OS8	Address Bus. If ALE is HIGH, the addresses become valid during phase 2 of the cycle before the one to which they refer and remain so during phase 1 of the referenced cycle. Their stable period may be controlled by ALE as described below.
ABE	I	Address bus enable. When this input is LOW, the address bus drivers (A[31:0]) are put into a high impedance state.
ABORT	I	Memory abort. This input allows the memory system to tell the processor that a requested access is not allowed. For ARM6x, the signal must be valid before the end of phase 1 of the cycle during which the memory transfer is attempted. On ARM7x and beyond, this signal must be valid before the end of phase 2.
ALE	I	Address latch enable. This input to the processor is used to control transparent latches on the address outputs. Normally the addresses change during phase 2 to the value required during the next cycle, but for direct interfacing to ROMs they are required to be stable to the end of phase 2. Taking ALE LOW until the end of phase 2 will ensure that this happens. If the system does not require address lines to be held in this way, ALE may be held permanently HIGH. The ALE latch is static, so ALE may be held LOW indefinitely.
BIGEND	I	Big Endian configuration. When this signal is HIGH, the processor treats words in memory as being in Big Endian format. When it is LOW, words in memory are treated as Little Endian.
CPA ¹	I	Coprocessor absent. A coprocessor which is capable of performing the operation that is requested, should take CPA LOW immediately. If CPA is high and NCPI is low at the rising edge of phase 2, then the VY86C060 will abort the coprocessor handshake, and take the undefined instruction trap. If CPA is LOW, the VY86C060 will busy-wait until CPB is LOW, and then complete the coprocessor instruction. If no coprocessors are fitted, CPA must be driven high.
CPB ²	I	Coprocessor busy. A coprocessor which is capable of performing the operation that is requested, but cannot commit to starting it immediately, should indicate this by driving CPB HIGH. When the coprocessor is ready to start, it should drive CPB LOW. The VY86C060 samples CPB on the rising edge of phase 2 whenever NCPI is low. If no coprocessors are fitted, CPB must be driven HIGH.
D[31:0]	I/OS8	Data bus. These are bidirectional signal paths which are used for data transfers between the processor and external memory. During read cycles (when NRW is LOW), the input data must be valid before the end of phase 2 of the transfer cycle. During write cycles (when NRW is HIGH), the output data will become valid during phase 1 and remain valid throughout phase 2 of the transfer cycle.
DATA32	I	32-bit Data configuration. When this signal is HIGH, the processor can access data in a 32-bit address space using address lines A[31:0]. When it is LOW the processor can access data from a 26-bit address space using A[25:0]. In this latter configuration the address lines A[31:26] are not used. Before changing DATA32, ensure that the processor is not about to access an address greater than &3FFFFFF in the next cycle.
DBE	I	Data bus enable. When this input is LOW, the data bus drivers (D[31:0]) are put into a high impedance state. The drivers will always be high impedance except during write operations, and DBE may be tied HIGH in systems that do not require the data bus for DMA or similar activities.
LATEABT ³	I	Late Abort. This signal controls the action of the processor on an ABORT exception. When it is HIGH (Late Abort), the modified base register of an aborted LDR, LDM, STR, or STM instruction is written back. This signal has no effect on when the ABORT signal is sampled. It is recommended that the Late Abort scheme be used where possible as only this scheme is used in ARM7x processors and beyond. However, ARM2, ARM2aS, and ARM3 support the Early Abort mechanism.
LOCK	OS8	Locked operation. When LOCK is HIGH, the processor is performing a "locked" memory access and the memory controller should wait until LOCK goes LOW before allowing another device to access the memory. LOCK changes during phase 2, and remains HIGH for the duration of the locked memory accesses. It is active only during the data swap instruction.
MCLK	I	Memory clock input. This clock times all memory accesses. The LOW (phase 1) or HIGH (phase 2) periods of MCLK may be stretched indefinitely when accessing slow peripherals; alternately, the NWAIT input may be used with a free-running MCLK to achieve the same effect.

Notes:

1. CPA must default HIGH when coprocessor cycles are not executed in order to enter the Undefined Instruction Exception.
2. CPB must default HIGH when coprocessor cycles are not executed in order to enter the Undefined Instruction Exception.
3. This pin only exists on the ARM6x processors, ARM7x processors and beyond are always configured for late abort.

SIGNAL DESCRIPTIONS (Cont.)

Name	Type	Description
NBW	OS8	NOT byte/word. This is an output signal used by the processor to indicate to the external memory system when a data transfer of a byte length is required. The signal is HIGH for word transfers and LOW for byte transfers and is valid for both read and write cycles. The signal will become valid during phase 2 of the cycle before the one during which the transfer will take place. It will remain stable throughout phase 1 of the transfer cycle.
NCPI	O4	NOT coprocessor instruction. When the VY86C060 executes a coprocessor instruction, it will take this output LOW. The action taken will depend on the CPA and CPB inputs.
NFIQ	I	NOT fast interrupt request. Same as NIRQ, but with higher priority. May be taken LOW asynchronously to interrupt the processor when the appropriate enable is active.
NIRQ	I	NOT interrupt request. An asynchronous interrupt request to the processor which causes it to be interrupted if taken LOW when the appropriate enable in the processor is active. The signal is level-sensitive and must be held LOW until a suitable response is received from the processor.
NMREQ	O4	NOT memory request. This signal, when LOW, indicates that the processor requires memory access during the following cycle. The signal becomes valid during phase 1, remaining valid through phase 2 of the cycle preceding that to which it refers.
NOPC	O4	NOT op-code fetch. When LOW, this signal indicates that the processor is fetching an instruction from memory. When HIGH, data is either being transferred or the VY86C060 is performing an internal cycle. The signal becomes valid during phase 2 of the previous cycle, remaining valid through phase 1 of the referenced cycle.
NRESET	I	NOT reset. This is a level-sensitive input signal that is used to start the processor from a known address. A LOW level will cause the instruction being executed to terminate abnormally. When NRESET becomes HIGH for at least one clock cycle, the processor will restart from address 0. NRESET must remain LOW (and NWAIT must remain HIGH) for at least two clock cycles. During the LOW period, the processor will perform dummy instruction fetches with the address incrementing from the point where reset was activated. The address value will overflow to zero if NRESET is held beyond the maximum address limit.
NRW	OS8	NOT read/write. When HIGH this signal indicates a processor write cycle; when LOW, a read cycle. It becomes valid during phase 2 of the cycle prior to the referenced cycle, and remains valid to the end of phase 1 of the referenced cycle.
NTRANS	OS8	NOT memory translate. When this signal is LOW, it indicates that the processor is in user mode. It may be used to tell memory management hardware when translation of the addresses should be turned on, or as an indicator of non-user mode activity.
NTRST	IP	NOT Test Reset. Active-low reset signal for the boundary scan logic. This input has an on-chip pull-up resistor to VDD. The timing of this and the following four boundary-scan signals are described in more detail later in this document.
NWAIT	I	NOT wait. When accessing slow peripherals, the VY86C060 can be made to wait for an integer number of MCLK cycles by driving NWAIT LOW. Internally, NWAIT is ANDed with the MCLK clock, and must only change when MCLK is LOW. If NWAIT is not used in a system, it may be tied HIGH.
PROG32	I	32-bit Program configuration. When this signal is HIGH, the processor can fetch instructions from a 32-bit address space using address lines A[31:0]. When it is LOW the processor fetches instructions from a 26-bit address space using A[25:0]. In this latter configuration the address lines A[31:26] are not used for instruction fetches. Before changing PROG32, ensure that the processor is in a 26-bit mode, and is not about to write to an address in the range 0 to &1F (inclusive) in the next cycle.
SEQ	O4	Sequential address. Will become HIGH when the address of the next memory cycle will be related to that of the last memory access. The new address will either be the same as, or four greater than the old one. The signal becomes valid during phase 1 and remains so through phase 2 of the cycle preceding that to which it refers. It may be used in combination with the low-order address lines to indicate that the next cycle can use a fast memory mode (for example DRAM page mode) and/or to bypass the address translation system.

**SIGNAL DESCRIPTIONS (Cont.)**

Name	Type	Description
TCK	IP	Test Clock. This input to the boundary-scan logic has an on-chip pull-up resistor to VDD.
TDI	IP	Test Data Input. This input to the boundary-scan logic has an on-chip pull-up resistor to VDD.
TDO	OS8	Test Data Output. Output from the boundary-scan logic.
TMS	IP	Test Mode Select. This input to the boundary-scan logic has an on-chip pull-up resistor to VDD.
VDD	P	Positive supply.
VSS	P	Supply ground.

Key to Signal Types

I	Input (TTL threshold)
IP	Input (TTL threshold) with pull-up resistor
O4	Output (4 mA drive) for VY86C06020FC-2/VY86C06040 and (8 mA drive) for VY86C060A
OS8	Output (8 mA slew-limited drive)
P	Power supply

CONFIGURATION AND MODE SELECTION

The VY86C060 supports a variety of operating configurations. Some are controlled by signal inputs and are known as the Hardware Configurations. Others may be controlled by software and are known as *operating modes*.

HARDWARE CONFIGURATION

The VY86C060 provides four hardware configuration inputs that may be changed while the processor is running. The inputs may only change during phase 2 of the clock cycle.

Two of the inputs (DATA32 and PROG32) allow one of three processor configurations to be selected as follows:

- (1) 26-bit program and data space – (DATA32 LOW, PROG32 LOW).

This configuration forces the VY86C060 to operate like the earlier ARM processors with 26-bit address space. The programmer's model for these processors applies, but the new instructions to access the CPSR and SPSR registers operate as detailed later in this document. In this configuration, it is impossible to select a 32-bit operating mode. All exceptions (including address exceptions) enter the exception handler in the appropriate 26-bit mode.

- (2) 26-bit program space and 32-bit data space – (DATA32 HIGH, PROG32 LOW). This is the same as the 26-bit program and data space configuration, but with address exceptions disabled to allow data transfer operations to access the full 32-bit address space.

- (3) 32-bit program and data space – (DATA32 HIGH, PROG32 HIGH). This configuration extends the address space to 32-bits, introduced broad changes in the programmer's model (as described below), and provides support for running existing 26-bit programs in the 32-bit environment.

The fourth processor configuration which is possible (26-bit data space and 32-bit program space) should not be selected.

The BIGEND signal controls whether the VY86C060 treats words in memory as being stored in Big Endian or Little Endian format. Memory is viewed as a linear collection of bytes numbered upwards from zero. Bytes 0 to 3 hold the first stored word, Bytes 4 to 7 the second, and so on.

In the Little Endian scheme, the least significant byte of a word is stored at the lowest numbered byte, and the most significant byte is stored at the highest numbered byte. Byte 0 of the memory system should be connected to data lines 7 through 0 (D[7:0]) in this scheme.

In the Big Endian scheme, the most significant byte of a word is stored at the lowest numbered byte, and the least significant byte is stored at the highest numbered byte. Byte 0 of the memory system should therefore be connected to data lines 31 through 24 (D[31:24]).

The LATEABT signal controls the processor's behavior when a data abort exception occurs. It only affects the behavior of LDR and STR instructions and is discussed more fully in the section about exceptions and the description of data transfer instructions.

OPERATING MODE SELECTION

When configured for 26-bit program space, the VY86C060 is limited to operating in one of four modes known as the 26-bit modes. These modes correspond to the modes of the earlier ARM processors and are known as User26, FIQ26, IRQ26, and Supervisor26.

When using a 32-bit program space, there are a total of 10 modes available. These are the four 26-bit modes described above, plus six more known as the 32-bit modes. These are User32, FIQ32, IRQ32, Supervisor32, Abort32, and Undefined32. These are the normal operating modes in this configuration. The 26-bit modes are only provided for backwards compatibility to allow execution of programs originally written for earlier ARM processors.

Notes:

1. The remainder of this document describes the VY86C060 when configured for 32-bit program and data space and operating in one of the 32-bit modes. It is recommended that all new designs using the VY86C060 should configure the processor in this way by setting PROG32 and DATA32 HIGH, and that all new code should be written to use only the 32-bit operating modes. It is also recommended that the LATEABT input be set HIGH so that the Late Abort exception mechanism is used.
2. Because the original VY86C060 instruction set has been modified to accommodate 32-bit operation, there are certain additional restrictions programmers must be aware of. These are indicated in the text by the words "shall" and "shall not".

PROGRAMMER'S MODEL

INTRODUCTION

The VY86C060 has a 32-bit data bus and a 32-bit address bus. The data types the processor supports are Bytes (eight bits) and Words (32 bits), where words must be aligned to four byte boundaries. Instructions are exactly one word, and data operations (e.g. ADD) are only performed on word quantities. Load and store operations can transfer either bytes or words.

The VY86C060 supports six modes of operation:

- (1) User mode: the normal program execution state
- (2) FIQ mode (fiq): designed to support a data transfer or channel process
- (3) IRQ mode (irq): used for general-purpose interrupt handling
- (4) Supervisor mode (svc): a protected mode for the operating system
- (5) Abort mode (abt): Entered after a data or instruction prefetch abort

(6) Undefined mode (und): entered when an undefined instruction is executed

Mode changes may be made under software control or may be brought about by external interrupts or exception processing. Most application programs will execute in User mode. The other modes, known as *privileged modes*, will be entered to service interrupts or exceptions or to access protected resources.

REGISTERS

The processor has a total of 37 registers made up of 31 general-purpose 32-bit registers and six status registers. At any one time, 16 general-purpose registers (R0 to R15) and one or two status registers are visible to the programmer. The visible registers depend on the processor mode, and the other registers (the *banked registers*) are switched in to support IRQ, FIQ, Supervisor, Abort, and Undefined mode processing. The register bank organization is shown below. The banked registers are shaded in the diagram.

All registers except R15 are general-purpose and may be used to hold data or address values. Register R15 holds the Program Counter (PC). When R15 is read, bits [1:0] are zero and bits [31:2] contain the PC. A seventeenth register the Current Program Status Register (CPSR) is also accessible. It contains condition code flags and the current mode bits, and may be thought of as an extension to the PC.

R14 is used as the subroutine link register and receives a copy of R15 when a Branch and Link instruction is executed. It may be treated as a general-purpose register at all other times. R14_svc, R14_irq, R14_fiq, R14_abt, and R14_und are used similarly to hold the return values of R15 when interrupts and exceptions arise, or when Branch and Link instructions are executed within interrupt or exception routines.

REGISTER ORGANIZATION

GENERAL REGISTERS AND PROGRAM COUNTER

User32 Mode	FIQ32 Mode	Supervisor32 Mode	Abort32 Mode	IRQ32 Mode	Undefined32 Mode
R0	R0	R0	R0	R0	R0
R1	R1	R1	R1	R1	R1
R2	R2	R2	R2	R2	R2
R3	R3	R3	R3	R3	R3
R4	R4	R4	R4	R4	R4
R5	R5	R5	R5	R5	R5
R6	R6	R6	R6	R6	R6
R7	R7	R7	R7	R7	R7

R10	R10_fiq	R10	R10	R10	R10
R11	R11_fiq	R11	R11	R11	R11
R12	R12_fiq	R12	R12	R12	R12
R13	R13_fiq	R13_svc	R13_abt	R13_irq	R13_und
R14	R14_fiq	R14_svc	R14_abt	R14_irq	R14_und
R15 (PC)	R15(PC)	R15(PC)	R15(PC)	R15(PC)	R15(PC)

PROGRAM STATUS CPSR REGISTERS

CPSR	CPSR	CPSR	CPSR	CPSR	CPSR
	SPSR_fiq	SPSR_svc	SPSR_abt	SPSR_irq	SPSR_und

FIQ mode has seven banked registers mapped to R8 - R14 (R8_fiq - R14_fiq). Many FIQ programs will not need to save any registers.

User mode, IRQ mode, Supervisor mode, Abort mode, and Undefined mode each have two banked registers mapped to R13 and R14. The two banked registers allow these modes to each have a private stack pointer and a link register. Supervisor, IRQ, Abort, and Undefined mode programs which require more than these two banked registers are expected to save some or all of the caller's registers (R0 to R12) on their respective stacks. They are then free to use these registers, which they will restore before returning to the caller. In addition, there are five SPSRs (Saved Program Status Registers) which are loaded with the CPSR when an exception occurs. There is one SPSR for each privileged mode.

The format of the Program Status Registers is shown below. The N, Z, C, and V bits are the *condition code flags*. The condition code flags in the CPSR may be changed as a result of arithmetic and logical operations in the processor and may be tested by all instructions to determine if the instruction is to be executed.

The I and F bits are the *interrupt disable bits*. The I bit disables IRQ interrupts when it is set, and the F bit disables FIQ interrupts when it is set. The [M[4:0]] *mode bits* determine the mode in which the processor operates. The interpretation of the mode bits is shown below. Not all combinations of the mode bits define a valid processor mode. Only those explicitly described shall be used.

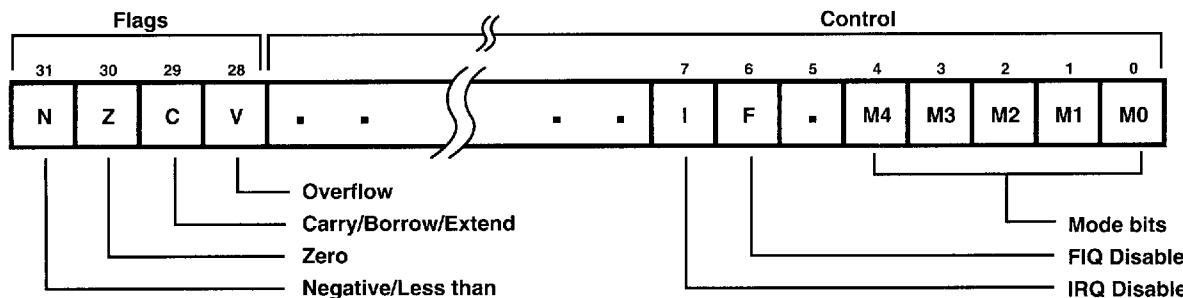

The bottom 28 bits of a PSR (incorporating I, F and M[4:0]) are known collectively as the *control bits*. The control bits will change when an exception arises

and can be manipulated by software when the processor is in a privileged mode. Unused bits in the PSRs are reserved and their state shall be preserved when changing the flag or control bits. Programs shall not rely on specific values from the reserved bits when checking the PSR status, since they may read as one or zero in future processors.

EXCEPTIONS

Exceptions arise whenever there is a need for the normal flow of program execution to be broken, so that (for example) the processor can be diverted to handle an interrupt from a peripheral. The processor state just prior to handling the exception must be preserved so that the original program can be resumed when the exception routine has completed. Many exceptions may arise at the same time.

FORMAT OF THE PROGRAM STATUS REGISTER (PSR)

MODE BITS

M[4:0]	Mode	Accessible Register Set	
10000	usr	PC, R14.. R0	CPSR
10001	fiq	PC, R14_fiq..R8_fiq, R7..R0	CPSR, SPSR_fiq
10010	irq	PC, R14_irq..R13_irq, R12..R0	CPSR, SPSR_irq
10011	svc	PC, R14_svc..R13_svc, R12..R0	CPSR, SPSR_svc
10111	abt	PC, R14_abt..R13_abt, R12..R0	CPSR, SPSR_abt
11011	und	PC, R14_und..R13_und, R12..R0	CPSR, SPSR_und

The VY86C060 handles exceptions by making use of the banked registers to save state. The old PC and CPSR contents are copied into the appropriate registers (R14 and SPSR), and the PC and mode bits in the CPSR bits are forced to a value that depends on the exception. Interrupt disable flags are set where required to prevent otherwise unmanageable nestings of exceptions. In the case of a re-entrant interrupt handler, R14 and the SPSR should be saved onto a stack in main memory before re-enabling the interrupt. When transferring the SPSR register to and from a stack, it is important to transfer the whole 32-bit value, not just the flag or control fields. When multiple exceptions arise simultaneously, a fixed priority determines the order in which they are handled.

FIQ

The FIQ (Fast Interrupt reQuest) exception is externally generated by taking the NFIQ input LOW. This input can accept asynchronous transitions, and is delayed by one clock cycle for synchronization before it can affect the processor execution flow. It is designed to support a data transfer or channel process, and has sufficient private registers to remove the need for register saving in such applications, minimizing the overhead of context switching. The FIQ exception may be disabled by setting the F flag in the CPSR (note that this is not possible from User mode). If the F flag is clear, the VY86C060 checks for a LOW level on the output of the FIQ synchronizer at the end of each instruction.

When a FIQ is detected, the VY86C060 performs the following:

- (1) Saves the address of the next instruction to be executed plus four in R14_fiq; saves CPSR in SPSR_fiq
- (2) Forces M[4:0]=%10001 (FIQ mode) and sets the F and I bits in the CPSR
- (3) Forces the PC to fetch the next instruction from address &1C

To return normally from FIQ, use SUBS PC, R14_fiq, #4 which will restore both the PC (from R14) and the CPSR (from SPSR_fiq) and resume execution of the interrupted code.

IRQ

The IRQ (Interrupt ReQuest) exception is a normal interrupt caused by a LOW level on the NIRQ input. This input can accept asynchronous transitions, and is delayed by one clock cycle for synchronization before it can affect the processor execution flow. It has a lower priority than FIQ, and is masked out when a FIQ sequence is entered. Its effect may be masked out at any time by setting the I bit in the PC (note that this is not possible from User mode). If the I flag is clear, VY86C060 checks for a LOW level on the output of the IRQ synchronizer at the end of each instruction.

When an IRQ is detected, the VY86C060 performs the following:

- (1) Saves the address of the next instruction to be executed plus four in R14_irq; saves CPSR in SPSR_irq
- (2) Forces M[4:0]=%10010 (IRQ mode) and sets the I bit in the CPSR
- (3) Forces the PC to fetch the next instruction from address &18

To return normally from IRQ, use SUBS PC, R14_irq, #4 which will restore both the PC and the CPSR and resume execution of the interrupted code.

Abort

The Abort signal comes from an external memory management system, and indicates that the current memory access cannot be completed. For instance, in a virtual memory system the data corresponding to the current address may have been moved out of memory onto a disk, and considerable processor activity may be required to recover the data before the access can be performed successfully. The VY86C060 checks for an Abort during memory access (N and S) cycles and distinguishes between two types of aborts.

- (i) If the abort occurred during an instruction prefetch (a Prefetch Abort), the prefetched instruction is marked as invalid but the abort exception does not occur immediately. If the

instruction is not executed, for example, as a result of a branch being taken while it is in the pipeline, no abort will occur. An abort will take place if the instruction reaches the head of the pipeline and is about to be executed.

- (ii) If the abort occurred during a data access (a Data Abort), the action depends on the instruction type.
 - (a) Data transfer instructions (LDR, STR) are aborted as though the instruction had not executed if the processor is a VY86C060 and is configured for Early Abort. When configured for Late Abort or the processor is a VY86C070, these instructions are able to write-back modified base registers and the Abort handler must be aware of this.
 - (b) The swap (SWP) instruction is aborted as though it had not executed.
 - (c) LDM and STM instructions complete, and if write-back is set, the base is updated. If the instruction would normally have overwritten the base with data (i.e. LDM with the base in the transfer list), this overwriting is prevented. All register overwriting is prevented after the Abort is indicated. R15 (which is always last to be transferred) is preserved in an aborted LDM instruction.

When either a prefetch or data abort occurs, the VY86C060 performs the following:

- (1) Saves the address of the aborted instruction plus 4 (for prefetch aborts) or 8 (for data aborts) in R14_abt; saves CPSR in SPSR_abt.
- (2) Forces M[4:0]=%10111 (Abort mode) and sets the I bit in the CPSR
- (3) Forces the PC to fetch the next instruction from either address &0C (prefetch abort) or address &10 (data abort).

To return after fixing the reason for the abort, use SUBS PC, R14_abt, #4 (for a prefetch abort) or SUBS PC, R14_abt, #8 (for a data abort). This will restore both the PC and the CPSR and retry the aborted instruction.

The abort mechanism allows a demand paged virtual memory system to be implemented when a suitable memory manager is available. The processor is allowed to generate arbitrary addresses. When the data at an address is unavailable, the memory manager signals an abort. The processor traps into system software, which must work out the cause of the abort, make the requested data available, and retry the aborted instruction. The application program needs no knowledge of the amount of memory available to it, nor is its state in any way affected by the abort.

Software Interrupt

The software interrupt instruction (SWI) is used for getting into Supervisor mode, usually to request a particular supervisor function. When a SWI is executed, the VY86C060 performs the following:

- (1) Saves the addresses of the SWI instruction plus 4 in R14_svc; saves CPSR in SPSR_svc
- (2) Forces M[4:0]=%10011 (Supervisor mode) and sets the I bit in the CPSR
- (3) Forces the PC to fetch the next instruction from address &08

To return from a SWI, use MOVS PC,R14_svc. This will restore the PC and CPSR and return to the instruction following the SWI.

Undefined Instruction Trap

When the VY86C060 executes a coprocessor instruction or an undefined instruction, it offers it to any coprocessors that may be present. If a coprocessor signals that it can perform this instruction but is busy at that moment, the VY86C060 will wait until the coprocessor is ready. If no coprocessor can handle the instruction, the VY86C060 will take the undefined instruction trap.

The trap may be used for software emulation of a coprocessor in a system that does not have the coprocessor hardware, or for general-purpose instruction set extension by software emulation.

When the VY86C060 takes the undefined instruction trap, it performs the following:

- (1) Saves the address of the Undefined or coprocessor instruction plus 4 in R14_und; saves CPSR in SPSR_und
- (2) Forces M[4:0]=%11011 (Undefined mode) and sets the I bit in the CPSR
- (3) Forces the PC to fetch the next instruction from address &04

To return from this trap after emulating the failed instruction, use MOVS PC,R14_und. This will restore the CPSR and return to the instruction following the undefined instruction.

Reset

When the NRESET signal goes LOW, the VY86C060 abandons the currently executing instruction and continues to fetch instructions from memory which it interprets as NOPs.

When NRESET goes HIGH again, the VY86C060 does the following:

- (1) Overwrites R14_svc and SPSR_svc by copying the current values of the PC and CPSR into them. The value of the saved PC and CPSR is not defined.
- (2) Forces M[4:0]=%10011 (Supervisor mode) and sets the I and F bits in the CPSR
- (3) Forces the PC to fetch the next instruction from address &00

VECTOR SUMMARY

Address	Exception	Mode on Entry
&00000000	Reset	Supervisor
&00000004	Undefined instruction	Undefined
&00000008	Software interrupt	Supervisor
&0000000C	Abort (prefetch)	Abort
&00000010	Abort (data)	Abort
&00000014	—reserved—	—
&00000018	IRQ	IRQ
&0000001C	FIQ	FIQ

These are byte addresses, and will normally contain a branch instruction pointing to the relevant routine. The FIQ routine might reside at &1C onwards, and thereby avoid the need for (and execution time of) a branch instruction.

The reserved entry is for an Address Exception vector which is only operative when the processor is configured for a 26-bit program space.

**Exception Priorities**

When multiple exceptions arise at the same time, a fixed priority system determines the order in which they will be handled:

- (1) Reset (highest priority)
- (2) Data abort
- (3) FIQ
- (4) IRQ
- (5) Prefetch abort
- (6) Undefined Instruction, Software interrupt (lowest priority)

Note that not all exceptions can occur at once. Undefined instruction and software interrupt are mutually exclusive since they each correspond to particular (non-overlapping) decodings of the current instruction.

If a data abort occurs at the same time as a FIQ, and FIQs are enabled (i.e. the F flag in the CPSR is clear), the

VY86C060 will enter the data abort handler and immediately proceed to the FIQ vector. A normal return from FIQ will cause the data abort handler to resume execution. Placing the data abort at a higher priority than FIQ is necessary to ensure that the transfer error does not escape detection. The time for this exception entry should be added to worst-case FIQ latency calculations.

Interrupt Latencies

The worst-case latency for FIQ consists of the longest time the request can take to pass through the synchronizer (*TSYNCMAX*), plus the time for the longest instruction to complete (*TLDM*), plus the time for address exception or data abort entry (*TEXC*), plus the time for FIQ entry (*TFIQ*). At the end of this time, the VY86C060 will be executing the instruction at &1C.

TSYNCMAX is three processor cycles, *TLDM* is 20 cycles, *TEXC* is three cycles, and *TFIQ* is two cycles. The total time is therefore 28 processor cycles (just over one microsecond in a system which uses a continuous 25-MHz processor clock). In a DRAM-based system running at 4 and 8 MHz, this time becomes 4.5 microseconds. If bus bandwidth is being used to support video or other DMA activity, the time will increase accordingly.

The maximum IRQ latency calculation is similar, but must allow for the fact that FIQ has higher priority and could delay entry into the IRQ handling routine for an arbitrary length of time.

The minimum latency for FIQ or IRQ consists of the shortest time the request can take through the synchronizer (*TSYNCMIN*) plus *TFIQ*. This is four processor cycles.

THE CONDITION FIELD

**Condition Field**

- 0000 = EQ – Z set (equal)
- 0001 = NE – Z clear (not equal)
- 0010 = CS – C set (unsigned higher or same)
- 0011 = CC – C clear (unsigned lower)
- 0100 = MI – N set (negative)
- 0101 = PL – N clear (positive or zero)
- 0110 = VS – V set (overflow)
- 0111 = VC – V clear (no overflow)
- 1000 = HI – C set and Z clear (unsigned higher)
- 1001 = LS – C clear or Z set (unsigned lower or same)
- 1010 = GE – N set and V set, or N clear and V clear (greater or equal)
- 1011 = LT – N set and V clear, or N clear and V set (less than)
- 1100 = GT – Z clear, and either N set and V set, or N clear and V clear (greater than)
- 1101 = LE – Z set, or N set and V clear, or N clear and V set (less than or equal)
- 1110 = AL – always
- 1111 = NV – never (reserved)

All VY86C060 instructions are conditionally executed (their execution may or may not take place depending on the values of the N, Z, C and V flags in the CPSR).

If the ALways condition is specified, the instruction will be executed irrespective of the flags. The NeVer class of condi-

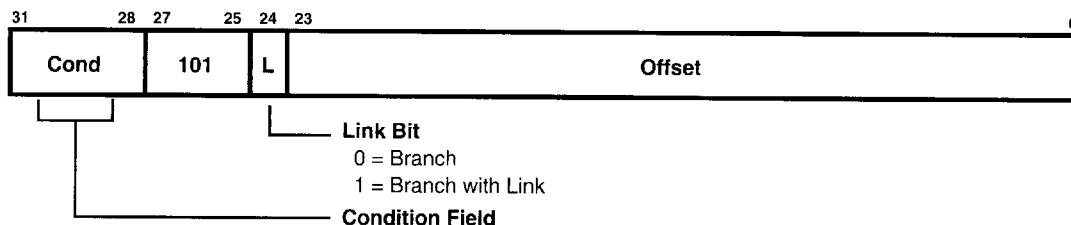

tion codes shall not be used as they will be redefined in future variants of the ARM architecture. If a NOP is required it is suggested that MOV R0, R0 be used.

The other condition codes have meanings as detailed above. For instance, code 0000 (EQual) causes the instruction to be executed only if the Z flag is

set. This would correspond to the case where a compare (CMP) instruction had found the two operands to be equal. If the two operands were different, the compare instruction would have cleared the Z flag and the instruction will not be executed.

BRANCH AND BRANCH WITH LINK (B, BL)

The instruction is only executed if the condition specified in the condition field is true.

Branch instructions contain a signed two's-complement 24-bit offset. This is shifted left two bits, sign extended to 32 bits, and added to the PC. The instruction can therefore specify a branch of +/- 32 Mbytes. The branch offset must take into account the prefetch operation, which causes the PC to be two words (eight bytes) ahead of the current instruction.

Branches beyond +/- 32 Mbytes must use an offset or absolute destination that has been previously loaded into a register. In this case, the PC should be manually saved in R14 if a Branch with Link type operation is required.

The Link Bit

Branch with Link writes the old PC into the link register (R14) of the current bank. The PC value written into R14 is adjusted to allow for the prefetch, and contains the address of the instruction following the branch and link instruction. Note that the CPSR is not saved with the PC.

To return from a routine called by Branch with Link use MOV PC, R14 if the link register is still valid or LDM Rn!, {..PC} if the link register has been saved onto a stack pointed to by Rn.

Assembler Syntax

B{L}{cond} <expression>

{L} is used to request the Branch with Link form of the instruction. If absent, R14 will not be affected by the instruction.

{cond} is a two-character mnemonic as shown in the Condition Field (EQ, NE, VS, etc.). If absent, then AL (ALways) will be used.

<expression> is the destination. The assembler calculates the offset.

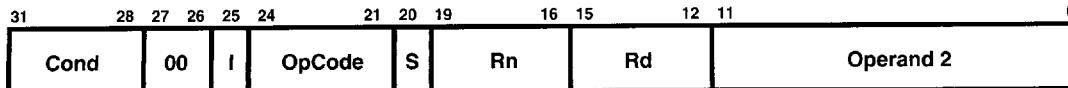

Items in {} are optional. Items in <> must be present.

Examples

here BAL here	; assembles to &EAFFFFFE (note effect of PC offset)
B there	; ALways condition used as default
CMP R1,#0	; compare R1 with zero and branch to fred if R1
BEQ fred	; was zero otherwise continue to next instruction
BL sub + ROM	; call subroutine at computed address
ADDS R1,#1	; add 1 to register 1, setting CPSR flags on the
BLCC sub	; result then call subroutine if the C flag is clear, ; which will be the case unless R1 held &FFFFFFF

Immediate Operand

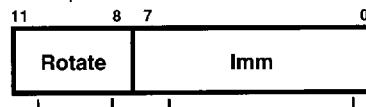

0 = Operand 2 is a Register

2nd Operand Register

Shift Amount and Type Applied to Rm

1 = Operand 2 is an Immediate Value

Unsigned 8-Bit Immediate Value

Rotate Right Amount Applied to Imm

Condition Field

The instruction is only executed if the condition specified in the condition field is true.

The instruction produces a result by performing a specified arithmetic or logical operation on one or two operands. The first operand is always a register (Rn). The second operand may be a

shifted register (Rm) or a rotated 8-bit immediate value (Imm) according to the value of the I bit in the instruction. The condition codes in the CPSR may be preserved or updated as a result of this instruction, according to the value of the S bit in the instruction. Certain opera-

tions (TST, TEQ, CMP, CMN) do not write the result to Rd. They are used only to perform tests and to set the condition codes on the result and always have the S bit set.

**Operations**

The operations supported are:

ASSEMBLER MNEMONICS

Mnemonic	OpCode	Action
AND	0000	operand1 AND operand2
EOR	0001	operand1 EOR operand2
SUB	0010	operand1 – operand2
RSB	0011	operand2 – operand1
ADD	0100	operand1 + operand2
ADC	0101	operand1 + operand2 + carry (CPSR C flag)
SBC	0110	operand1 – operand2 + carry – 1
RSC	0111	operand2 – operand1 + carry – 1
TST	1000	as AND, but result is not written
TEQ	1001	as EOR, but result is not written
CMP	1010	as SUB, but result is not written
CMN	1011	as ADD, but result is not written
ORR	1100	operand1 OR operand2
MOV	1101	operand2 (operand1 is ignored)
BIC	1110	operand1 AND NOT operand2 (Bit clear)
MVN	1111	NOT operand2 (operand1 is ignored)

CPSR Flags

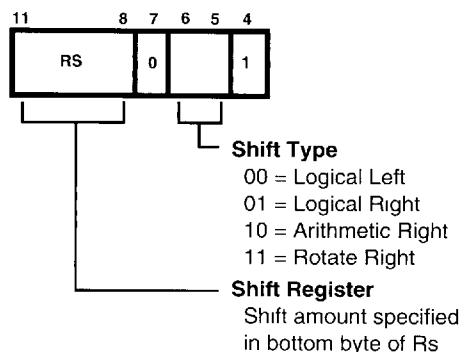

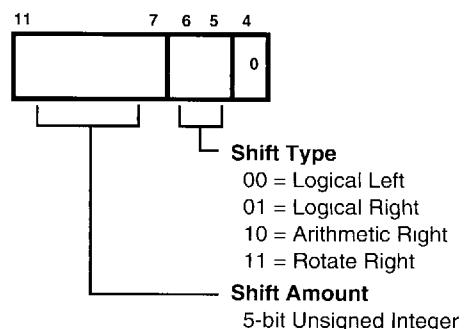

The data processing operations may be classified as logical or arithmetic. The logical operations (AND, EOR, TST, TEQ, ORR, MOV, BIC, MVN) perform the logical action on all corresponding bits of the operand or operands to produce the result. If the S bit is set (and Rd is not R15, see below), the V flag in the CPSR will be unaffected, the C flag will be set to the carry out from the barrel shifter (or preserved when the shift operation is LSL #0), the Z flag will be set if and only if the result is all zeros, and the N flag will be set to the logical value of Bit 31 of the result.

The arithmetic operations (SUB, RSB, ADD, ADC, SBC, RSC, CMP, CMN) treat each operand as a 32-bit integer

(either unsigned or two's-complement signed, the two are treated in the same manner). If the S bit is set (and Rd is not R15), the V flag in the CPSR will be set if a carry occurs into Bit 31 of the result; this may be ignored if the operands were considered unsigned, but can be used to determine an overflow condition, if the operands were two's-complement signed. The C flag will be set to the carry out of Bit 31 of the ALU, the Z flag will be set if and only if the result was zero, and the N flag will be set to the value of Bit 31 of the result (indicating a negative result if the operands are considered to be two's-complement signed).

Shifts

When the second operand is specified to be a shifted register, the operation of the barrel shifter is controlled by the Shift field in the instruction. This field indicates the type of shift to be performed (logical left or right, arithmetic right or rotate right). The amount by which the register should be shifted may be contained in an immediate field in the instruction, or in the bottom byte of another register (other than R15):

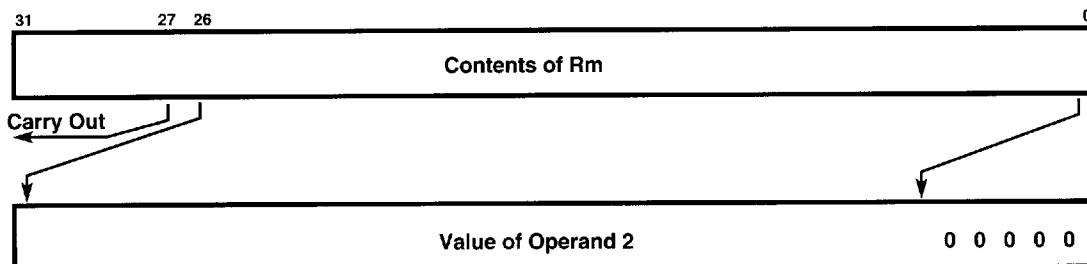

**Instruction Specified Shift Amount**

When the shift amount is specified in the instruction, it is contained in a five-bit field which may take any value from 0 to 31. A logical shift left (LSL) takes the contents of Rm and moves each bit by the specified amount to a more sig-

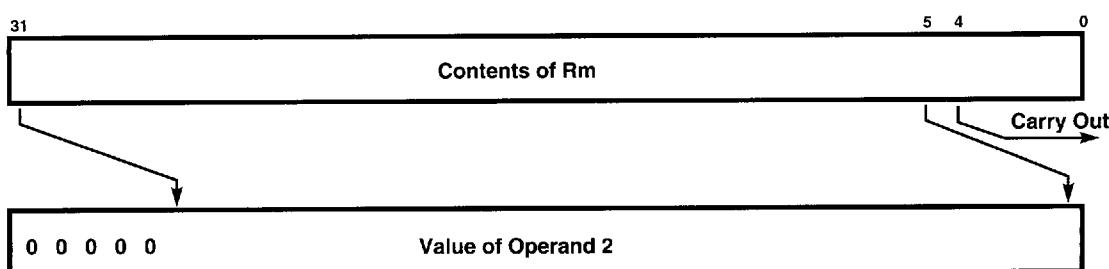

nificant position. The least significant bits of the result are filled with zeros, and the high bits of Rm (which do not map into the result) are discarded. However, the least significant discarded bit becomes the shifter carry output that

may be latched into the C bit of the CPSR when the ALU operation is in the logical class (see previous page). For example, the effect of LSL #5 is:

Note that LSL #0 is a special case, where the shifter carry out is the old value of the CPSR C flag. The contents of Rm are used directly as the second operand.

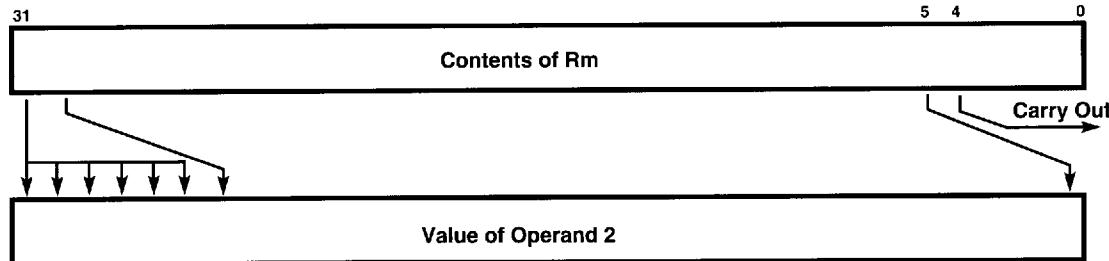

A logical shift right (LSR) is similar, but the contents of Rm are moved to less significant positions in the result. LSR #5 has this effect:

The form of the shift field that might be expected to correspond to LSR #0 is used to encode LSR #32, which has a zero result with Bit 31 of Rm as the carry output. Logical shift right zero is

redundant as it is the same as logical shift left zero, so the assembler will convert LSR #0 (and ASR #0 and ROR #0) into LSL #0, and allow LSR #32 to be specified.

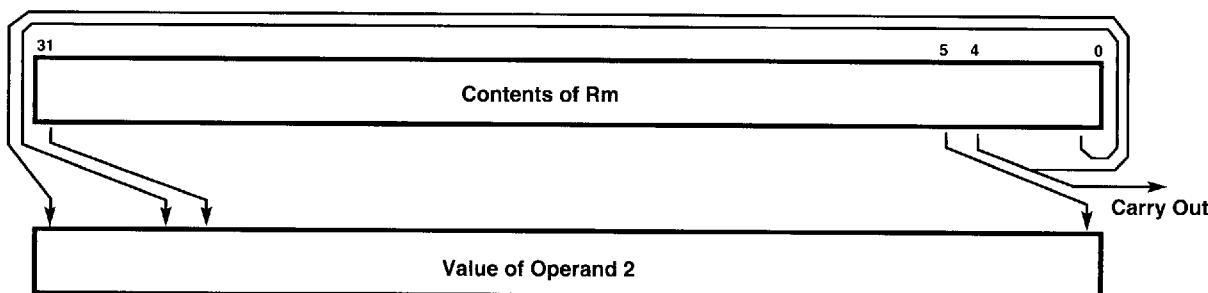

An arithmetic shift right (ASR) is similar to logical shift right, except that the high bits are filled with Bit 31 of Rm instead of zeros. This preserves the sign in two's-complement notation. For example, ASR #5:

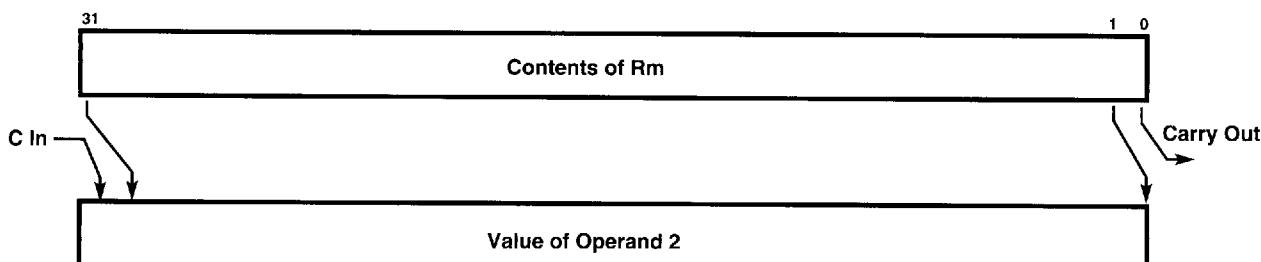

The form of the shift field that might be expected to give ASR #0 is used to encode ASR #32. Bit 31 of Rm is again used as the carry output, and each bit of operand 2 is also equal to Bit 31 of Rm. The result is therefore all ones or all zeros, according to the value of Bit 31 of Rm.

Rotate right (ROR) operations reuse the bits that 'overshoot' in a logical shift right operation by reintroducing them at the high end of the result, in place of the zeros used to fill the high end in logical right operations. For example, ROR #5:

The form of the shift field that might be expected to give ROR #0 is used to encode a special function of the barrel shifter, rotate right extended (RRX).

This is a rotate right by one bit position of the 33-bit quantity formed by appending the CPSR C flag to the most significant end of the contents of Rm:

Register Specified Shift Amount

Only the least significant byte of the contents of Rs is used to determine the shift amount. Rs can be any general register other than R15.

If this byte is zero, the unchanged contents of Rm will be used as the second operand, and the old value of the CPSR C flag will be passed on as the shifter carry output.

If the byte has a value between 1 and 31, the shifted result will exactly match that of an instruction specified shift with the same value and shift operation.

If the value in the byte is 32 or more, the result will be a logical extension of the shifting processes described above:

- (i) LSL by 32 has result zero, carry out equal to bit 0 of Rm.
- (ii) LSL by more than 32 has result zero, carry out zero.
- (iii) LSR by 32 has result zero, carry out equal to Bit 31 of Rm.
- (iv) LSR by more than 32 has result zero, carry out zero.
- (v) ASR by 32 or more has result filled with, and carry out equal to, Bit 31 of Rm.
- (vi) ROR by 32 has result equal to Rm, carry out equal to Bit 31 of Rm.
- (vii) ROR by n where n is greater than 32 will give the same result and carry out as ROR by n-32; therefore, repeatedly subtract 32 from n until the amount is in the range 1 to 32 and see above.

Note that a zero in Bit 7 of an instruction with a register controlled shift is mandatory; a one in this bit will cause the instruction to be a multiply or a data swap instruction.

**Immediate Operand Rotates**

The Immediate Operand Rotate field is a four-bit unsigned integer that specifies a shift operation on the eight bit immediate value. The immediate value is zero extended to 32 bits, and then subject to a rotate right by twice the value in the rotate field. This enables many common constants to be generated, for example all powers of two.

Writing to R15

When Rd is a register other than R15, the condition code flags in the CPSR may be updated from the ALU flags as described above.

When Rd is register R15, and the S flag in the instruction is not set, the result of the operation is placed in R15 and the CPSR is unaffected.

When Rd is register R15, and the S flag is set, the result of the operation is placed in R15 and the SPSR corresponding to the current mode is moved to the CPSR. This allows state changes that atomically restore both PC and CPSR. This form of instruction is not a valid instruction in User mode.

Using R15 as an Operand

If R15 (the PC) is used as an operand in a data processing instruction the register is used directly.

The PC value will be the address of the instruction, plus eight or 12 bytes due to instruction prefetching. If the shift amount is specified in the instruction, the PC will be eight bytes ahead. If a register is used to specify the shift amount, the PC will be 12 bytes ahead.

The TEQ, TST, CMP, and CMN Opcodes

These instructions do not write the result of their operation to any register but do set flags in the CPSR. An assembler shall always set the S flag for these instructions even if it is not specified in the mnemonic.

The TEQP form of the instruction used in earlier versions of the architecture shall not be used in the VY86C060 while using 32-bit modes. The PSR transfer operations should be used instead. If the TEQP form of instruction is used in these modes, its effect is to move SPSR_<mode> to CPSR if the processor is in a privileged mode, and to do nothing if in User mode.

Assembler Syntax

- (i) MOV, MVN – single operand instructions
 <opcode>{cond}{S} Rd,<Op2>
- (ii) CMP,CMN,TEQ,TST – instructions which do not produce a result.
 <opcode>{cond} Rn,<Op2>
- (iii) AND, EOR, SUB, RSB, ADD, ADC, SBC, RSC, ORR, BIC
 <opcode>{cond}{S} Rd,Rn,<Op2>

where <Op2> is Rm{,<shift>} or, <#expression>

{cond} – two-character condition mnemonic.

{S} – set condition codes if S present (implied for CMP, CMN, TEQ, TST).

Rd, Rn and Rm are expressions evaluating to a register number.

If <#expression> is used, the assembler will attempt to generate a shifted immediate 8-bit field to match the expression. If this is impossible, it will give an error.

<shift> is <shiftname> <register> or <shiftname> #expression, or RRX (rotate right one bit with extend).

<shiftname>s are: ASL, LSL, LSR, ASR, ROR.

(ASL is a synonym for LSL, the two assemble to the same code.)

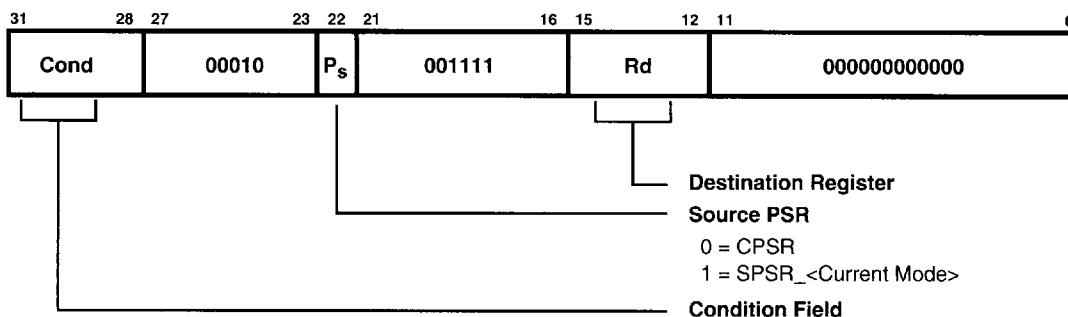

Examples

ADDEQ R2,R4,R5	; if the Z flag is set make R2:=R4+R5
TEQS R4,#3	; test R4 for equality with 3 ; (The S is redundant, it is automatically ; inserted by the assembler)
SUB R4, R5, R7, LSR R2	; logical right shift R7 by the number in ; the bottom byte of R2, subtract the result ; from R5, and put the answer into R4
MOV PC, R14	; return from subroutine
MOVS PC, R14	; return from exception & restore CPSR_<mode>

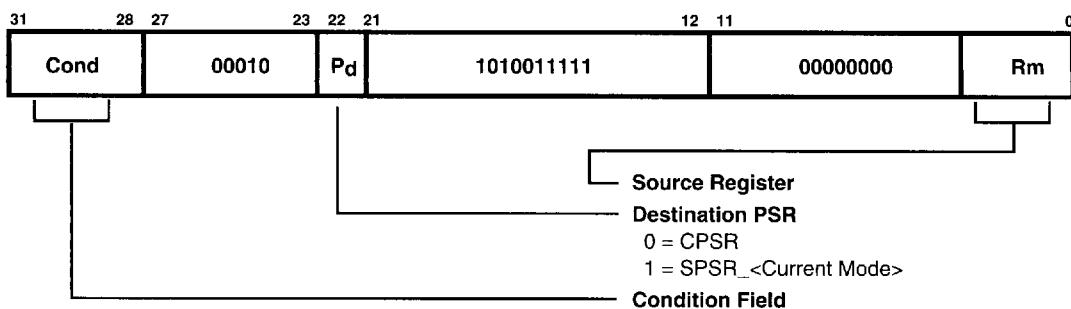

PSR TRANSFER (MRS, MSR)

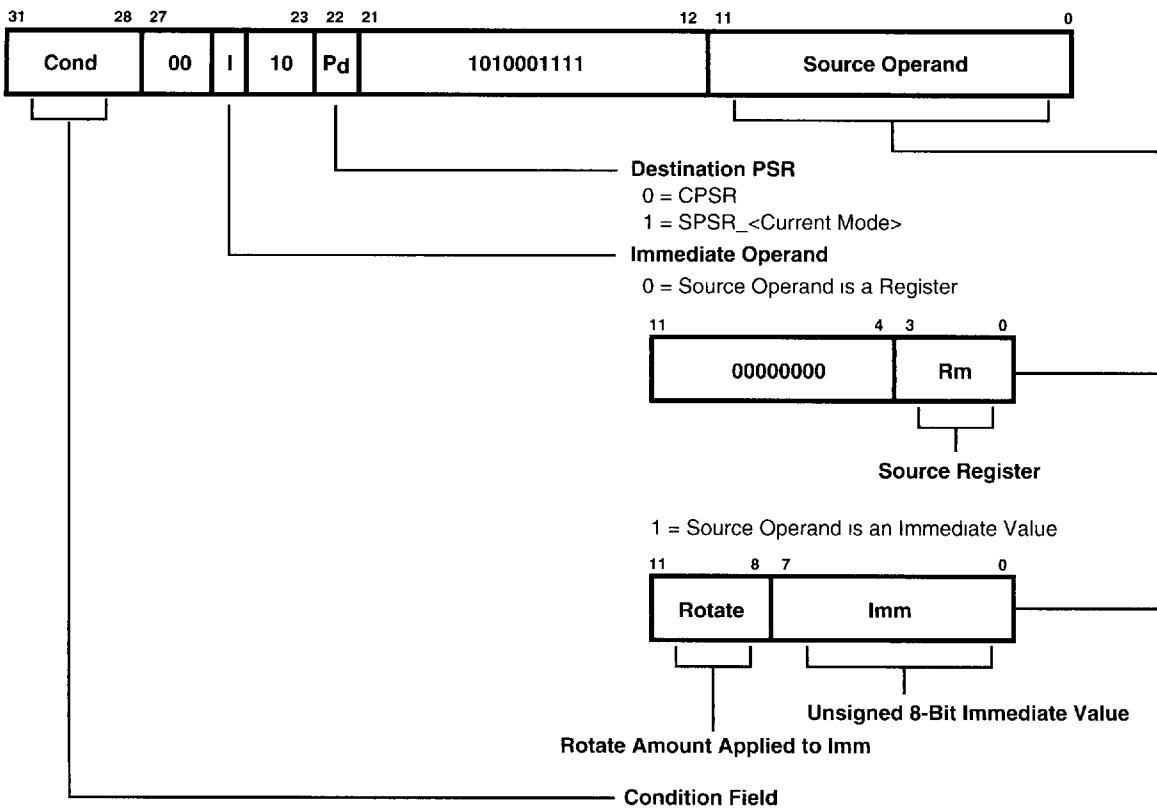

MRS (Transfer PSR Contents to a Register)

MSR (Transfer Register Contents to PSR)

MSR (Transfer Register Contents or Immediate Value to PSR Flag Bits Only)

The PSR transfer instructions allow access to the CPSR and SPSR registers, and are only executed if the condition is true.

The MRS instruction allows the contents of the CPSR or SPSR_<mode> to be moved to a general register. The MSR instruction allows the contents of a general register to be moved to the CPSR or SPSR_<mode> register. R15 shall not be specified as the source or destination register.

The MSR instruction also allows an immediate value, or register contents, to be transferred to the condition code flags (N,Z,C, and V) of CPSR or SPSR_<mode> without affecting the control bits. In this case, the top four bits of the specified register contents, or 32-bit immediate value, are written to the top four bits of the relevant PSR.

Operand Restrictions

In User mode, the control bits of the CPSR are protected from change, so only the condition code flags of the CPSR can be changed. In privileged modes the entire CPSR can be changed.

Which SPSR register is accessed depends on the mode at the time of execution. For example, only SPSR_fiq is accessible when the processor is in FIQ mode.

No attempt shall be made to access an SPSR in User mode, since no such register exists.

Reserved Bits

Only 11 bits of the PSR are defined in the VY86C060 (N,Z,C,V,I,F & M[4:0]). The remaining bits (= PSR[27:8,5]) are reserved for use in future versions of the processor. To ensure the maximum compatibility between VY86C060 programs and future processors, the following rules should be observed:

- The reserved bits shall be preserved when changing the value in a PSR.
- Programs shall not rely on specific values from the reserved bits when checking the PSR status, since they may read as one or zero in future processors.

A read-modify-write strategy should therefore be used when altering the control bits of any PSR register. This involves transferring the appropriate PSR register to a general register using the MRS instruction, changing only the relevant bits and then transferring the modified value back to the PSR register using the MSR instruction.

e.g. The following sequence performs a mode change:

MRS	Rtmp,CPSR	; take a copy of the CPSR
BIC	Rtmp,Rtmp,#&1F	; clear the mode bits
ORR	Rtmp,Rtmp,#new_mode	; select new mode
MSR	CPSR,Rtmp	; write-back the modified CPSR

When the aim is simply to change the condition code flags in a PSR, an immediate value can be written directly to the flag bits without disturbing the control bits.

e.g. The following instruction sets the N,Z,C and V flags:

MSR	CPSR_flg,#&F0000000	; set all the flags regardless of ; their previous state (does not ; affect any control bits)
-----	---------------------	---

No attempt shall be made to write an 8-bit immediate value into the whole PSR since such an operation cannot preserve the reserved bits.

Assembler Syntax

(1) MRS - transfer PSR contents to a register

MRS{cond} Rd,<psr>

(2) MSR - transfer register contents to PSR

MSR{cond} <psr>,Rm

(3) MSR - transfer register contents to PSR flag bits only

MSR{cond} <psrf>,Rm

The most significant four bits of the register contents are written to the N,Z,C & V flags respectively.

(4) MSR - transfer immediate value to PSR flag bits only

MSR{cond} <psrf>,<#expression>

The expression should symbolize a 32-bit value of which the most significant four bits are written to the N,Z,C & V flags respectively.

{cond} - two-character condition mnemonic.

Rd and Rm are expressions evaluating to a register number other than R15.

<psr> is CPSR, CPSR_all, SPSR or SPSR_all. (CPSR and CPSR_all are synonyms as are SPSR and SPSR_all)

<psrf> is CPSR_flg or SPSR_flg

Where <#expression> is used, the assembler will attempt to generate a shifted immediate 8-bit field to match the expression. If this is impossible, it will give an error.

Examples

In User mode the instructions behave as follows:

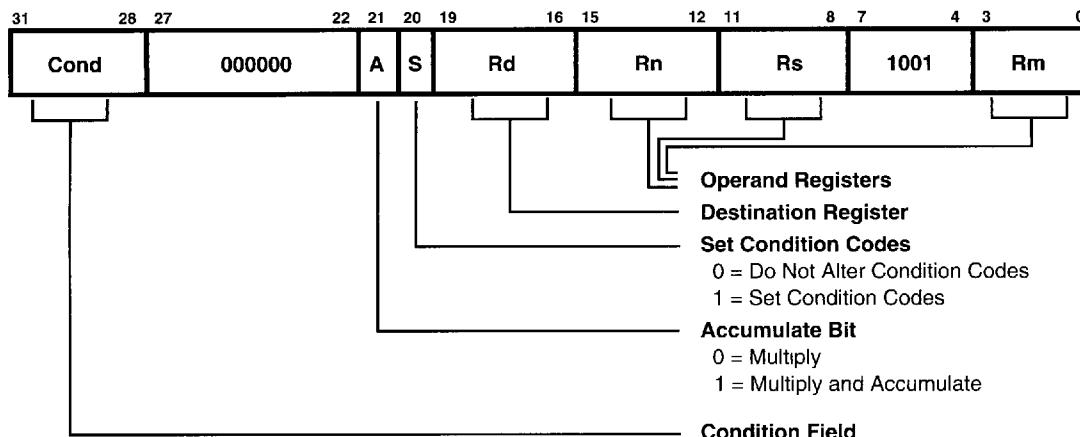

```
MSR    CPSR_all,Rm          ; CPSR[31:28] <- Rm [31:28]
MSR    CPSR_flg,Rm          ; CPSR[31:28] <- Rm [31:28]
MSR    CPSR_flg,#&A0000000  ; CPSR[31:28] <- &A
                           ; (i.e. set N,C; clear Z,V)
MRS    Rd,CPSR              ; Rd[31:0] <- CPSR[31:0]
```

In privileged modes the instructions behave as follows:

```
MSR    CPSR_all,Rm          ; CPSR[31:0] <- Rm[31:0]
MSR    CPSR_flg,Rm          ; CPSR[31:28] <- Rm[31:28]
MSR    CPSR_fiq,#&50000000  ; CPSR[31:28] <- &5
                           ; (i.e. set Z,V; clear N,C)
MRS    Rd,CPSR              ; Rd[31:0] <- CPSR[31:0]
MSR    SPSR_all,Rm          ; SPSR_<mode>[31:0] <- Rm[31:0]
MSR    SPSR_flg,Rm          ; SPSR_<mode>[31:28] <- Rm[31:28]
MSR    SPSR_flg,#&C0000000  ; SPSR_<mode>[31:28] <- &C
                           ; (i.e. set N,Z; clear C,V)
MRS    Rd,SPSR              ; Rd[31:0] <- SPSR_<mode>[31:0]
```

MULTIPLY AND MULTIPLY-ACCUMULATE (MUL, MLA)

The instruction is only executed if the condition specified in the condition field is true.

The multiply and multiply-accumulate instructions use a two-bit modified Booth's algorithm to perform integer multiplication. They give the least significant 32 bits of the product of two 32-bit operands, and may be used to synthesize higher precision multiplications.

The multiply form of the instruction is $Rd := Rm * Rs$. Rn is ignored, and should be set to zero for compatibility with possible future upgrades to the instruction set.

The multiply-accumulate form is $Rd := Rm * Rs + Rn$, which can save an explicit ADD instruction in some circumstances.

Both forms of the instruction work on operands which may be considered as signed (two's-complement) or unsigned integers.

Operand Restrictions

Due to the way the Booth's algorithm has been implemented, certain combinations of operand registers should be avoided. (A warning will be issued by the assembler.)

The destination register (Rd) should not be the same as the Rm operand register, as Rd is used to hold intermediate values and Rm is used repeatedly during the multiply. A MUL will give a zero result if $Rm = Rd$, and a MLA will give a meaningless result. R15 shall not be used as an operand or as the destination register.

CPSR Flags

Setting the CPSR flags is optional, and is controlled by the S bit in the instruction. The N and Z flags are set correctly on the result (N is equal to Bit 31 of the result, Z is set if and only if the result is zero), the V flag is unaffected by the instruction (as for logical data processing instructions), and the C flag is set to a meaningless value.

Assembler Syntax

MUL{cond}{S} Rd, Rm, Rs

MLA{cond}{S} Rd, Rm, Rs, Rn

{cond} – two-character condition mnemonic.

{S} – set condition codes if S present.

Rd, Rm, Rs and Rn are expressions evaluating to a register number other than R15.

Examples

MUL R1, R2, R3 ; $R1 := R2 * R3$

MLAEQS R1, R2, R3, R4 ; conditionally $R1 := R2 * R3 + R4$,
; setting condition codes

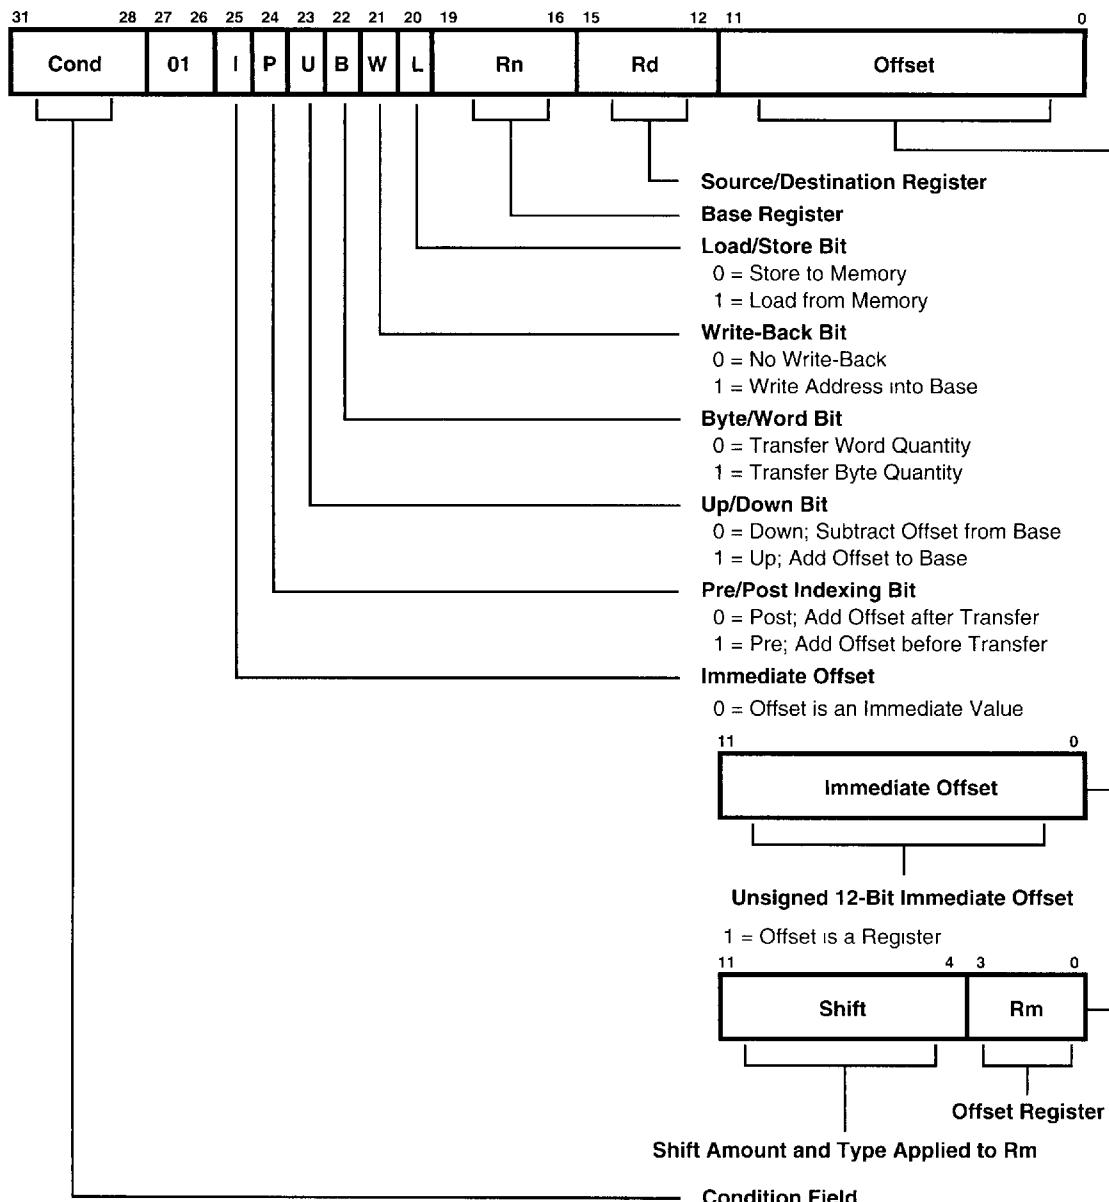

The multiply instruction may be used to synthesize higher precision multiplications. For instance, to multiply two 32-bit integers and generate a 64-bit result:

MUL64	MOV	a1, A, LSR #16	; a1:=top half of A
	MOV	D, B, LSR #16	; D:=top half of B
	BIC	A, A, a1, LSL #16	; A:=bottom half of A
	BIC	B, B, D, LSL #16	; B:=bottom half of B
	MUL	C, A, B	; low section of result
	MUL	B, a1, B	;) middle sections
	MUL	A, D, A	;) of result
	MUL	D, a1, D	; high section of result
	ADDS	A, B, A	; add middle sections ; (couldn't use MLA as we need C correct)
	ADDC	S D, D, #&10000	; carry from above add
	ADDS	C, C, A, LSL #16	; C is now bottom 32 bits of product
	ADC	D, D, A, LSR #16	; D is top 32 bits

(A, B are registers containing the 32-bit integers; C, D are registers for the 64-bit result; a1 is a temporary register. A and B are overwritten during the multiply.)

SINGLE DATA TRANSFER (LDR, STR)

The instruction is only executed if the condition specified in the condition field is true.

The single data transfer instructions are used to load or store single bytes or words of data. The memory address used in the transfer is calculated by adding an offset to or subtracting an offset from a base register. The result of this calculation may be written back into the base register if 'auto-indexing' is required.

Offsets and Auto-Indexing

The offset from the base may be either a 12-bit unsigned binary immediate value in the instruction, or a second register (possibly shifted in some way). The offset may be added to (U=1) or subtracted from (U=0) the base register Rn. The offset modification may be performed either before (pre-indexed, P=1) or after (post-indexed, P=0) the base is used as the transfer address.

The W bit gives optional auto increment and decrement addressing modes. The modified base value may be written back into the base (W=1), or the old

base value may be kept (W=0). In the case of post-indexed addressing, the write-back bit is redundant (and usually set to zero), since the old base value can be retained by setting the offset to zero. Therefore, post-indexed data transfers always write-back the modified base. The only use of the W bit in a post-indexed data transfer is in privileged mode where setting the W bit forces non-privileged mode for the transfer, allowing the operating system to generate a user address in a system where memory management hardware makes suitable use of this hardware.

Shifted Register Offset

The eight shift control bits are described in the data processing instructions. The register specified shift amounts are not available in this instruction class.

Bytes and Words

This instruction class may be used to transfer a byte (B=1) or a word (B=0) between a VY86C060 register and memory.

The action of LDR(B) and STR(B) instructions is influenced by the bigend configuration signal to the processor. The two possible configurations are described below.

Little Endian Configuration

A byte load (LDRB) expects the data on D[7:0] if the supplied address is on a word boundary, on D[15:8] if it is a word address plus one byte, and so on. The selected byte is placed in the bottom eight bits of the destination register, and the remaining bits of the register are filled with zeros.

A byte store (STRB) repeats the bottom eight bits of the source register four times across D[31:0]. The external memory system should activate the appropriate byte subsystem to store the data.

A word load (LDR) will normally use a word aligned address. However, an address offset from a word boundary will cause the data to be rotated into the register so that the addressed byte occupies Bits 0 to 7. Half-words accessed at offsets 0 and 2 from the word boundary will be correctly loaded into Bits 0 through 15 of the register. Two shift operations are then required to clear or to sign extend the upper 16-bits.

A word store (STR) should generate a word aligned address. The word presented to the data bus is not affected if the address is not word aligned. That is, Bit 31 of the register being stored always appears on D[31].

Big Endian Configuration

A byte load (LDRB) expects the data on D[31:24] if the supplied address is on a word boundary, on D[23:16] if it is a word address plus one byte, and so on. The selected byte is placed in the bottom eight bits of the destination register and the remaining bits of the register are filled with zeros.

A byte store (STRB) repeats the bottom eight bits of the source register four times across D[31:0]. The external memory system should activate the appropriate byte subsystem to store the data.

A word load (LDR) should generate a word aligned address. An address offset of 0 or 2 from a word boundary will cause the data to be rotated into the register so the addressed byte occupies Bits 31 through 24. Half-words accessed at these offsets will be correctly loaded into Bits 16 through 31 of the register. A shift operation is then required to move (and optionally sign extend) the data into the bottom 16 bits. An address offset of 1 or 3 from a word boundary will cause the data to be rotated into the register so the addressed byte occupies Bits 15 through 8.

A word store (STR) should generate a word aligned address. The word presented to the data bus is not affected if the address is not word aligned. That is, Bit 31 of the register being stored always appears on D[31].

Use of R15

Write-back shall not be specified if R15 is specified as the base register (Rn). When using R15 as the base register, one must remember that it contains an address eight bytes on from the address of the current instruction.

R15 shall not be specified as the register offset (Rm).

When R15 is the source register (Rd) of a register store (STR) instruction, the stored value will be the address of the instruction plus 12.

Data Aborts

A transfer to or from a legal address may cause problems for a memory management system. For instance, in a system that uses virtual memory, the required data may be absent from main memory. The memory manager can signal a problem by taking the processor abort signal HIGH, whereupon the data transfer instruction will be prevented from changing the processor state and the Data Abort trap will be

taken. It is up to the system software to resolve the cause of the problem, then the instruction can be restarted and the original program continued.

The VY86C060 supports two types of Data Abort processing (depending on the lateabt configuration input). When configured for Early Aborts, any base register write-back which would have occurred is prevented from happening in the event of an Abort. When configured for Late Aborts, this write-back is allowed to take place and the Abort handler must correct this before allowing the instruction to be re-executed.

Restriction on the Use of Base Register

When configured for late aborts, the following code is very difficult to unwind as Rm gets updated before the abort handler is entered. In certain circumstances it may be impossible to calculate the initial value.

<LDR | STR> Rd, [Rn], {+/-}Rn{,<shift>}

A post-indexed LDR/STR where Rm=Rn shall not be used.

**Assembler Syntax**

<LDR | STR>{cond}{B} {T}Rd,<Address>

LDR – load from memory into a register.

STR – store from a register into memory.

{cond} – two-character condition mnemonic.

{B} – if B is present then byte transfer, otherwise word transfer.

{T} - if T is present the W bit will be set in a post-indexed instruction forcing non-privileged mode for the transfer cycle. T is not allowed when a pre-indexed addressing mode is specified or implied.

Rd is an expression evaluating to a valid register number.

<Address> can be:

- (i) An expression which generates an address:

<expression>

The assembler will attempt to generate an instruction using the PC as a base and a corrected immediate offset to address the location given by evaluating the expression. This will be a PC relative, pre-indexed address. If the address is out of range, an error will be generated.

- (ii) A pre-indexed addressing specification:

[Rn] offset of zero

[Rn,<#expression>]{!} offset of <expression> bytes

[Rn,{+/-}Rm{,<shift>}]{!} offset of +/- contents of index register, shifted by <shift>.

- (iii) A post-indexed addressing specification:

[Rn],<#expression> offset of <expression> bytes

[Rn],{+/-}Rm{,<shift>} offset of +/- contents of index register, shifted as by <shift>.

Rn and Rm are expressions evaluating to a valid register number. NOTE if Rn is R15 then the assembler will subtract eight from the offset value to allow for pipelining. In this case, base write-back shall not be specified.

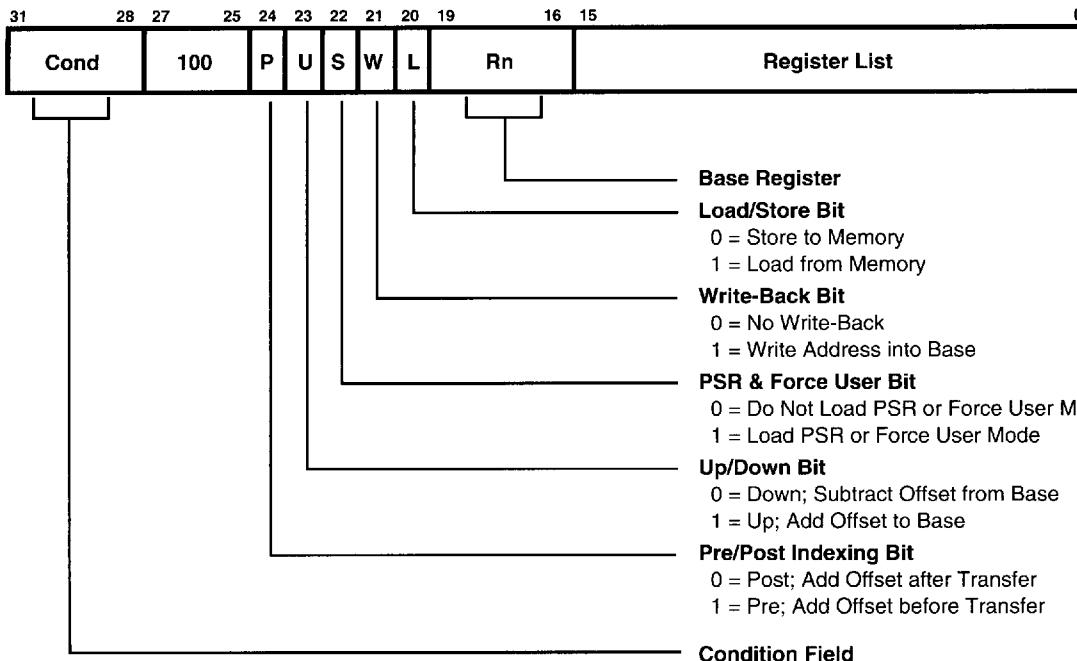

<shift> is a general shift operation (see section on Data Processing Instructions on page 13). Note that the shift amount may not be specified by a register.

{!} write-back the base register (set the W bit) if ! is present.

Examples	STR	R1, [BASE,INDEX]!	; store R1 at BASE+INDEX (both of which are ; registers) and write-back address to BASE
	STR	R1, [BASE],INDEX	; store R1 at BASE and write-back ; BASE+INDEX to BASE
	LDR	R1, [BASE, #16]	; load R1 from contents of BASE+16. ; Don't write-back
	LDR	R1, [BASE,INDEX,LSL #2]	; load R1 from contents of BASE+INDEX*4
	LDREQB	R1, [BASE,#5]	; conditionally load byte at BASE+5 into ; R1 bits 0 to 7, filling Bits 8 to 31 ; with zeros
PLACE	STR	R1, PLACE	; generate PC relative offset to address ; PLACE

BLOCK DATA TRANSFER (LDM, STM)

The instruction is only executed if the condition specified in the condition field is true.

Block data transfer instructions are used to load (LDM) or store (STM) any subset of the currently visible registers. They support all possible stacking modes, maintaining full or empty stacks which can grow up or down memory. These are very efficient instructions for saving or restoring context, or for moving large blocks of data around main memory.

The Register List

The instruction can cause the transfer of any registers in the current bank. (Non-user mode programs can also transfer

to and from the user bank. See page 26). The register list is a 16-bit field in the instruction, with each bit corresponding to a register. A logical one in Bit 0 of the register field will cause R0 to be transferred, a logical zero will cause it not to be transferred. Similarly, Bit 1 controls the transfer of R1, and so on.

Any subset of the registers, or all the registers, may be specified. The only restriction is that the register list should not be empty.

Whenever R15 is stored to memory the stored value is the address of the STM instruction plus 12.

Addressing Modes

The transfer addresses are determined by the contents of the base register (Rn), the pre/post bit (P) and the up/down bit (U). The registers are transferred in the order lowest to highest, so R15 (if in the list) will always be transferred last. The lowest register also gets transferred to/from the lowest memory address.

Address Alignment

The address should normally be a word aligned quantity and non-word aligned addresses do not affect the instruction. However, the bottom two bits of the address will appear on A[1:0] and might be interpreted by the memory system.

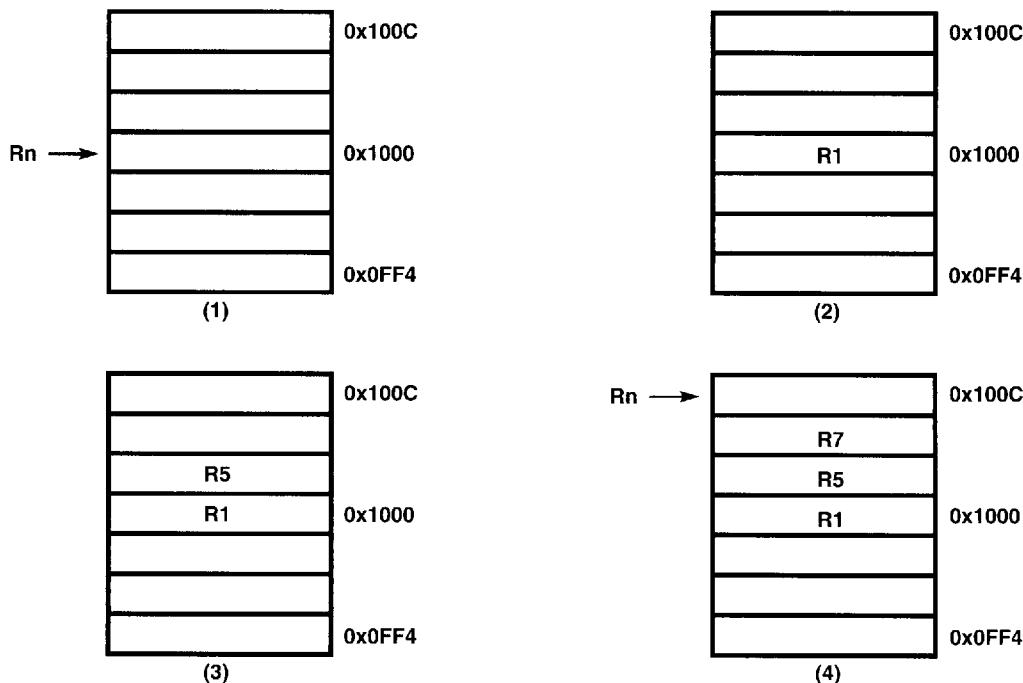

By way of illustration, consider the transfer of R1, R5, and R7 in the case where Rn=1000H and write-back of the modified base is required (W=1). The

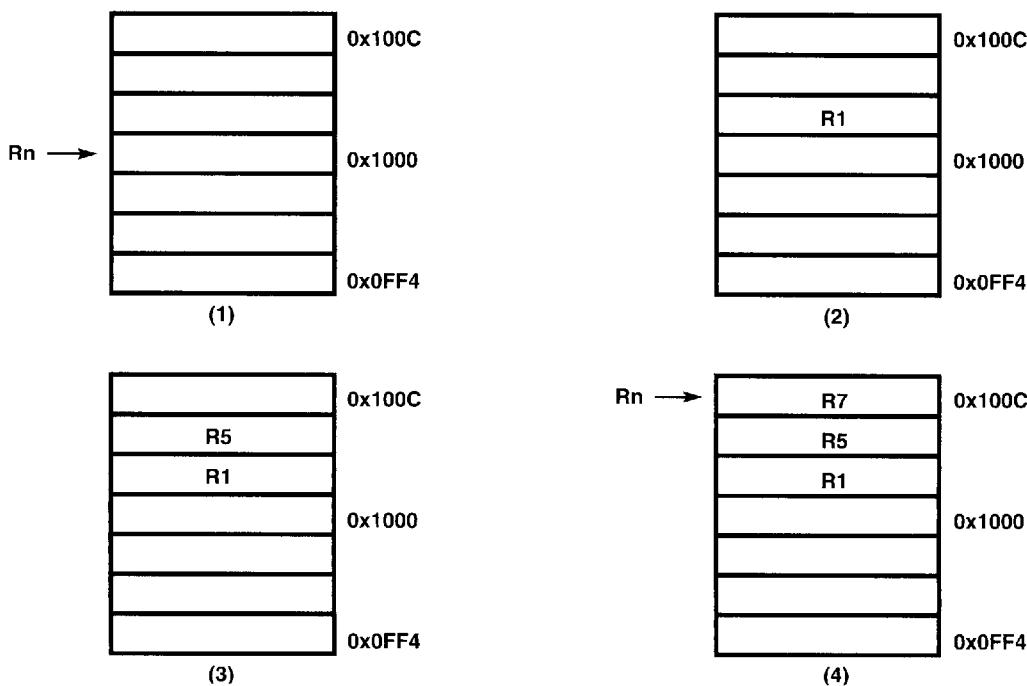

following figures show the sequence of register transfers, the addresses used, and the value of Rn after the instruction has completed.

(In all cases, had write-back of the modified base not been required (W=0), Rn would have retained its initial value of 1000H unless it was also in the transfer list of a load multiple register instruction, when it would have been overwritten with the loaded value.)

POST-INCREMENT ADDRESSING

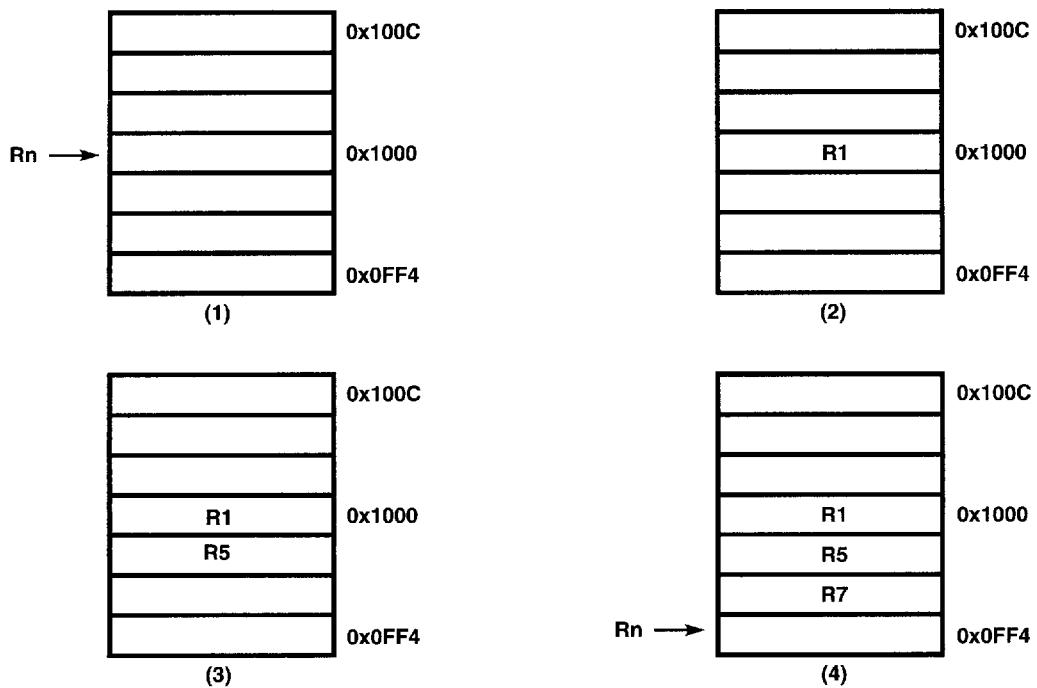

PRE-INCREMENT ADDRESSING

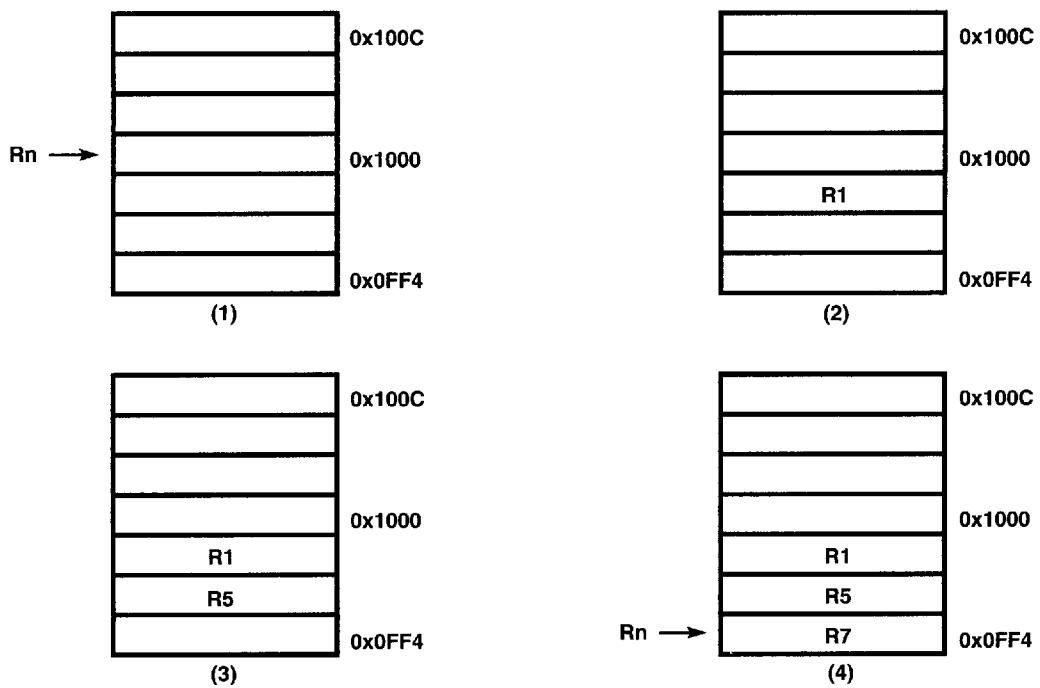

POST-DECREMENT ADDRESSING

PRE-DECREMENT ADDRESSING

**Use of the S Bit**

When the S bit is set in a LDM/STM instruction, its meaning depends on whether or not R15 is in the transfer list and on the type of instruction. The S bit should only be set if the instruction is to execute in a privileged mode.

LDM With R15 in Transfer List and S Bit Set (Mode Changes)

If the instruction is a LDM then SPSR_<mode> is transferred to CPSR at the same time as R15 is loaded.

STM With R15 in Transfer List and S Bit Set (User Bank Transfer)

The registers transferred are taken from the User bank rather than the bank corresponding to the current mode. This is useful for saving the user state on process switches. Base write-back shall not be used when this mechanism is employed.

R15 Not in List and S Bit Set (User Bank Transfer)

For both LDM and STM instructions, the User bank registers are transferred rather than the register bank corresponding to the current mode. This is useful for saving the user state on process switches. Base write-back shall not be used when this mechanism is employed.

When the instruction is LDM, care must be taken not to read from a banked register during the following cycle (inserting a NOP after the LDM will ensure safety).

Inclusion of the Base in the Register List

When write-back is specified, the base is written back at the end of the second cycle of the instruction. During a STM, the first register is written out at the start of the second cycle. A STM which includes storing the base, with the base as the first register to be stored, will therefore store the unchanged value, whereas with the base second or later in the transfer order, will store the modified value. A LDM will always overwrite the updated base if the base is in the list.

Use of R15 as the Base

R15 shall not be used as the base register in any LDM or STM instruction.

DATA ABORTS

Some legal addresses may be unacceptable to a memory management system, and the memory manager can indicate a problem with an address by taking the abort signal HIGH. This can happen on any transfer during a multiple register load or store, and must be recoverable if the VY86C060 is to be used in a virtual memory system.

The state of the lateabt input does not affect the behavior of LDM and STM instructions in the event of an Abort exception.

ABORTS DURING STM INSTRUCTIONS

If the abort occurs during a store multiple instruction, the VY86C060 takes little action until the instruction completes, whereupon it enters the data abort trap. The memory manager is responsible for preventing erroneous writes to the memory. The only change to the internal state of the processor will be the modification of the base register if write-back was specified. This must be reversed by software (and the cause of the abort resolved) before the instruction may be retried.

Assembler Syntax

<LDM | STM>{cond}<FD | ED | FA | EA | IA | IB | DA | DB> RN{!},<Rlist>{^}
{cond} – two character condition mnemonic.

Rn is an expression evaluating to a valid register number.

<Rlist> can be either a list of registers and register ranges enclosed in {} (e.g. {R0, R2-R7, R10}), or an expression evaluating to the 16-bit operand.

{!} if present requests write-back (W=1), otherwise W=0.

{^} if present set S bit to load the CPSR along with the PC, or force transfer of user bank when in privileged mode.

ABORTS DURING LDM INSTRUCTIONS

When the VY86C060 detects a data abort during a load multiple instruction, it modifies the operation of the instruction to ensure that recovery is possible.

(i) Overwriting of registers stops when the abort happens. The aborting load will not take place but earlier ones may have overwritten registers. The PC is always the last register to be written and will always be preserved.

(ii) The base register is restored, to its modified value if write-back was requested. This ensures recoverability in the case where the base register is also in the transfer list, and may have been overwritten before the abort occurred.

The data abort trap is taken when the load multiple has completed. The system software must undo any base modification (and resolve the cause of the abort) before restarting the instruction.

**ADDRESSING MODE NAMES**

There are different assembler mnemonics for each of the addressing modes, depending on whether the instruction is being used to support stacks or for other purposes. The equivalences between the names and the values of the bits in the instruction are:

Name	Stack	Other	L Bit	P Bit	U Bit
Pre-increment load	LDMED	LDMIB	1	1	1
Post-increment load	LDMFD	LDMIA	1	0	1
Pre-decrement load	LDMEA	LDMDB	1	1	0
Post-decrement load	LDMFA	LDMDA	1	0	0
Pre-increment store	STMFA	STMIB	0	1	1
Post-increment store	STMEA	STMIA	0	0	1
Pre-decrement store	STMFD	STMDB	0	1	0
Post-decrement store	STMED	STMDA	0	0	0

FD, ED, FA, EA define pre/post indexing and the up/down bit by reference to the form of stack required. The F and E refer to a "full" or "empty" stack, i.e. whether a pre-index has to be done (full) before storing to the stack. The A and D refer to whether the stack is ascending or descending. If ascending, a STM will go up and LDM down. If descending, the opposite is true.

IA, IB, DA, DB allow control when LDM/STM are not being used for stacks and simply mean Increment After, Increment Before, Decrement After, Decrement Before.

Examples

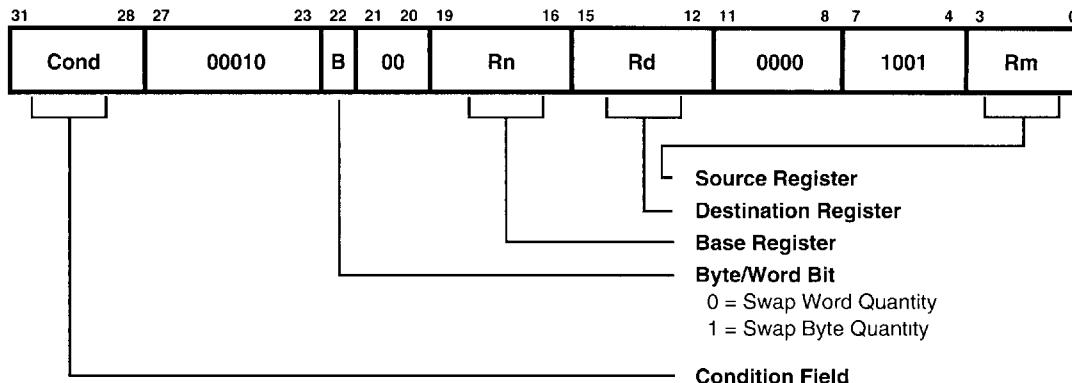

LDMFD SP!, {R0, R1, R2}	; unstack 3 registers
STMIA BASE, {R0-R15}	; save all registers
LDMFD SPI!, {R15}	; R15 <- (SP), CPSR unchanged
LDMFD SPI!, {R15}^	; R15 <- (SP), CPSR <- SPSR_mode (allowed only ; in privileged modes)
STMFD R13, {R0-R14}^	; Save user mode regs on stack (allowed only ; in privileged modes)

These instructions may be used to save state on subroutine entry, and restore it efficiently on return to the calling routine:

STMED SP!, {R0-R3, R14}	; save R0 to R3 to use as workspace ; and R14 for returning
BL somewhere	; this nested call will overwrite R14
LDMED SP!, {R0-R3, R15}	; restore workspace and return

SINGLE DATA SWAP (SWP)

This instruction is only executed if the condition specified in the condition field is true.

The data swap instruction is used to swap a byte or word quantity between a register and external memory. This instruction is implemented as a memory read followed by a memory write that are locked together. The processor cannot be interrupted until both operations have completed, and the memory manager is warned to treat them as inseparable. This class of instruction is particularly useful for implementing software semaphores.

The swap address is determined by the contents of the base register (Rn). The processor first reads the contents of the swap address. Then it writes the contents of the source register (Rm) to the swap address, and stores the old memory contents in the destination register (Rd). The same register may be specified as both the source and destination.

The lock output goes HIGH for the duration of the read and write operations to signal to the external memory manager that they are locked together, and should be allowed to complete without interruption. This is important in multi-processor systems where the swap instruction is the only indivisible instruction which may be used to implement semaphores. Control of the memory must not be removed from a processor while it is performing a locked operation.

Bytes and Words

This instruction class may be used to swap a byte (B=1) or a word (B=0) between a VY86C060 register and memory. The SWP instruction is implemented as a LDR followed by a STR, and the action of these is as described in the section on single data transfers. In particular, the description of Big and Little Endian configuration applies to the SWP instruction.

Use of R15

R15 shall not be used as an operand (Rd, Rn or Rs) in a SWP instruction.

Data Aborts

If the address used for the swap is unacceptable to a memory management system, the memory manager can flag the problem by driving abort HIGH. This can happen on either the read or the write cycle (or both). In either case, the data swap instruction will be prevented from changing the processor state and the Data Abort trap will be taken. It is up to the system software to resolve the cause of the problem, then the instruction can be restarted and the original program continued.

Because no base register write-back is allowed, the behavior of an aborted SWP instruction is the same regardless of the state of the LATEABT configuration input.

Assembler Syntax

<SWP>{cond}{B} Rd, Rm, [Rn]

{cond} – two-character condition mnemonic.

{B} – if B is present then byte transfer, otherwise word transfer.

Rd, Rm, Rn are expressions evaluating to valid register numbers.

Examples

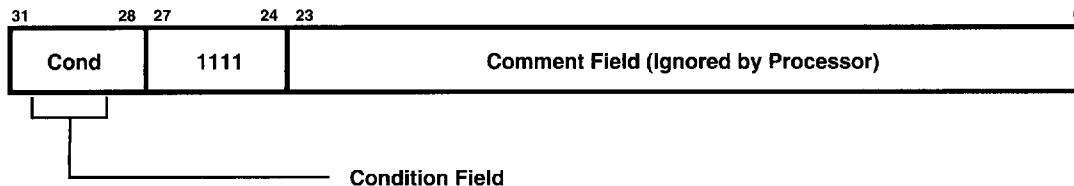

SWP R0, R1, [BASE] ; load R0 with the contents of BASE, and ; store R1 at BASE

SWPB R2, R3, [BASE] ; load R2 with the byte at BASE, and ; store Bits 0 to 7 of R3 at BASE

SWPEQ R0, R0, [BASE] ; conditionally swap the contents of BASE ; with R0

SOFTWARE INTERRUPT (SWI)

The instruction is only executed if the condition specified in the condition field is true.

The software interrupt instruction is used to enter Supervisor mode in a controlled manner. The instruction causes the software interrupt trap to be taken, which effects the mode change. The PC is forced to a fixed value (&08) and the CPSR is saved in SPSR_svc.

If this address is suitably protected (by external memory management hardware) from modification by the user, a fully protected operating system may be constructed.

Return From the Supervisor

The PC is saved in R14_svc upon entering the software interrupt trap, with the PC adjusted to point to the word after the SWI instruction. MOVS PC,R14_svc will return to the calling program and restore the CPSR.

Note that the link mechanism is not re-entrant, so if the supervisor code wishes to use software interrupts within itself, it must first save a copy of the return address and SPSR.

Comment Field

The bottom 24 bits of the instruction are ignored by the processor, and may be used to communicate information to the supervisor code. For instance, the supervisor may look at this field and use it to index into an array of entry points for routines that perform the various supervisor functions.

Assembler Syntax

`SWI{cond} <expression>`

{cond} – two character condition mnemonic.

<expression> is evaluated and placed in the comment field (which is ignored by VY86C060).

Examples

<code>SWI</code>	<code>ReadC</code>	; get next character from read stream
<code>SWI</code>	<code>Writel+“K”</code>	; output a “K” to the write stream
<code>SWINE</code>	<code>0</code>	; conditionally call supervisor ; with 0 in comment field

The above examples assume that suitable supervisor code exists, for instance:

<code>&08 B Supervisor</code>	; SWI entry point
<code>EntryTable</code>	; addresses of supervisor routines

`& ZeroRtn`
`& ReadCRtn`
`& WritelRtn`
 ...

`Zero * 0`

`ReadC * 256`

`Writel * 512`

`Supervisor`

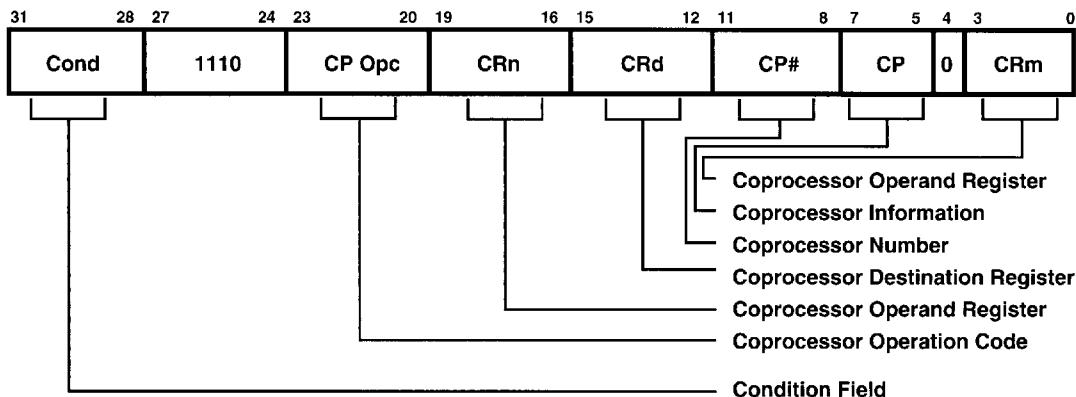

; SWI has routine required in Bits 8–23 and data (if any) in Bits 0–7.

; Assumes R13_svc points to a suitable stack

<code>STM R13, {R0-R2, R14}</code>	; save work registers and return address
<code>LDR R0, [R14, #-4]</code>	; get SWI instruction
<code>BIC R0, R0, #&FF000000</code>	; clear top 8 bits
<code>MOV R1, R0, LSR #8</code>	; get routine offset
<code>ADR R2, EntryTable</code>	; get start address of entry table
<code>LDR R15, [R2, R1, LSL #2]</code>	; branch to appropriate routine
<code>WritelRtn</code>	; enter with character in R0 Bits 0–7
<code>.....</code>	
<code>LDM R13, {R0-R2, R15}^</code>	; restore workspace and return

COPROCESSOR DATA OPERATIONS

COPROCESSOR DATA OPERATIONS (CDP)

The instruction is only executed if the condition specified in the condition field is true.

This class of instruction is used to tell a coprocessor to perform some internal operation. No result is communicated back to the VY86C060, and it will not wait for the operation to complete. The coprocessor could contain a queue of such instructions awaiting execution, and their execution can overlap other VY86C060 activity allowing the coprocessor and the VY86C060 to perform independent tasks in parallel.

The Coprocessor Fields

Only Bit 4 and Bits 24 to 31 are significant to VY86C060; the remaining bits are used by coprocessors. The above field names are used by convention, and particular coprocessors may redefine the use of all fields except CP# as appropriate. The CP# field is used to contain an identifying number (in the range 0 to 15) for each coprocessor, and a coprocessor will ignore any instruction which does not contain its number in the CP# field.

The conventional interpretation of the instruction is that the coprocessor should perform an operation specified in the CP Opc field (and possibly in the CP field) on the contents of CRn and CRm, and place the result in CRd.

Assembler Syntax

CDP{cond} CP#, <expression1>, CRd, CRn, CRm{, <expression2>}

{cond} – two character condition mnemonic.

CP# – the unique number of the required coprocessor.

<expression1> – evaluated to a constant and placed in the CP Opc field.

CRd, CRn and CRm are expressions evaluating to a valid coprocessor register number.

<expression2> – where present is evaluated to a constant and placed in the CP field.

Examples

CDP 1, 10, CR1, CR2, CR3

; request coproc 1 to do operation 10

; on CR2 and CR3, and put the result in CR1

CDPEQ 2, 5, CR1, CR2, CR3, 2

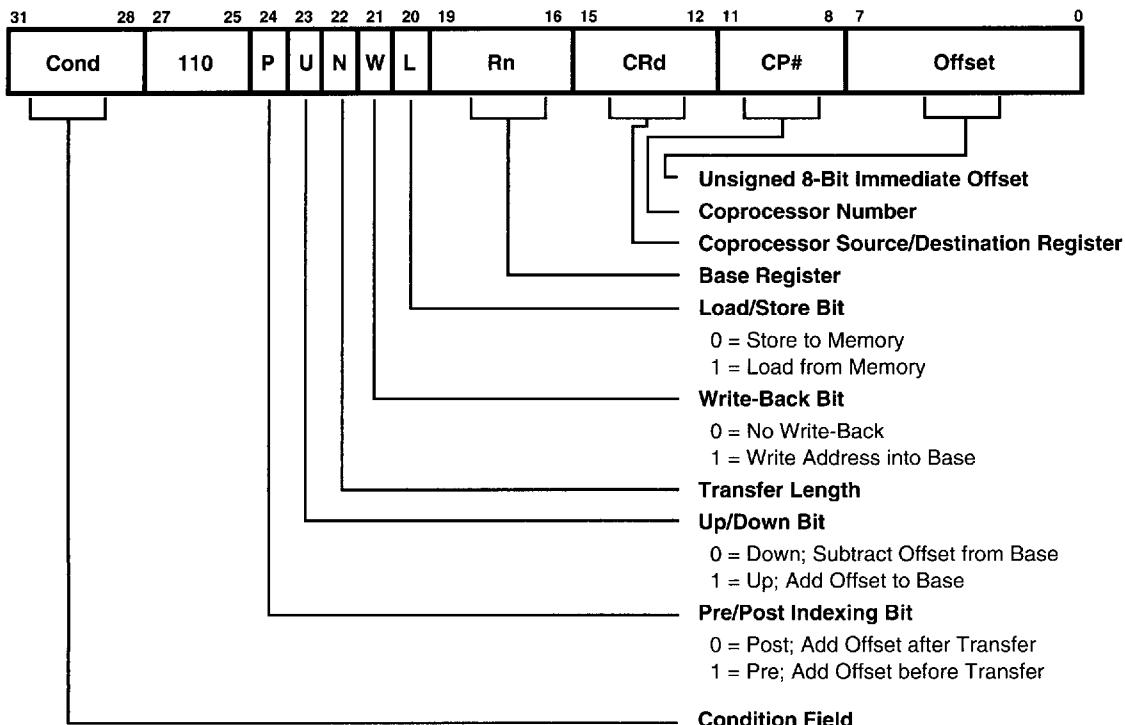

; if Z flag is set request coproc 2 to do

; operation 5 on CR2 and CR3,

; and put the result in CR1

COPROCESSOR DATA TRANSFERS (LDC, STC)

The instruction is only executed if the condition specified in the condition field is true.

This class of instruction is used to transfer one or more words of data between a coprocessor and main memory. The VY86C060 is responsible for supplying the memory address, and the coprocessor supplies or accepts the data and controls the number of words transferred. This class of instruction is used to load (LDC) or store (STC) a subset of a coprocessor's registers directly to memory.

The Coprocessor Fields

The CP# field is used to identify the coprocessor that is required to supply or accept the data. A coprocessor will only respond if its number matches the contents of this field.

The CRd field and the N bit contain information for the coprocessor which may be interpreted in different ways by different coprocessors, but by convention CRd is the register to be transferred

(or the first register where more than one is to be transferred), and the N bit is used to choose one of two transfer length options. For instance, N=0 could select the transfer of a single register, and N=1 could select the transfer of all the registers for context switching.

Addressing Modes

The VY86C060 is responsible for providing the address used by the memory system for the transfer, and the addressing modes available are a subset of those used in single data transfer instructions. Note, however, that the immediate offsets are 8 bits wide and specify word offsets for coprocessor data transfers, whereas they are 12 bits wide and specify byte offsets for single data transfers.

The 8-bit unsigned immediate offset is shifted left 2 bits and either added to (U=1) or subtracted from (U=0) the base register (Rn); this calculation may be performed either before (P=1) or after (P=0) the base is used as the transfer address. The modified base value may be overwritten back into the base regis-

ter (if W=1), or the old value of the base may be preserved (W=0). Note that post-indexed addressing modes require explicit setting of the W bit, unlike LDR and STR which always write-back when post-indexed.

The value of the base register, modified by the offset in a pre-indexed instruction, is used as the address for the transfer of the first word. The second word (if more than one is transferred) will go to or come from an address one word (4 bytes) higher than the first transfer, and the address will be incremented by one word for each subsequent transfer.

**Address Alignment**

The base address should normally be a word-aligned quantity. The bottom 2 bits of the address will appear on A[1:0] and might be interpreted by the memory system.

Use of R15

If Rn is R15, the value used will be the address of the instruction plus 8 bytes. Base write-back shall not be specified.

Data Aborts

If the address is legal but the memory manager generates an abort, the data abort trap will be taken. The write-back of the modified base will take place, but all other processor state will be preserved. The coprocessor is partly responsible for ensuring that the data transfer can be restarted after the cause of the abort has been resolved, and must ensure that any subsequent actions it undertakes can be repeated when the instruction is retried.

The state of the lateabt input does not affect the behavior of LDC and STC instructions in the event of an Abort exception.

Assembler Syntax

<LDCISTC>{cond}{L} CP#,CRd,<Address>

LDC – load from memory to coprocessor.

STC – store from coprocessor to memory.

{L} – when present perform long transfer (N=1), otherwise perform short transfer (N=0).

{cond} – two character condition mnemonic.

CP# – the unique number of the required coprocessor.

CRd is an expression evaluating to a valid coprocessor register number.

<Address> can be:

- (i) An expression which generates an address:

<expression>

The assembler will attempt to generate an instruction using the PC as a base and a corrected immediate offset to address the location given by evaluating the expression. This will be a PC-relative, pre-indexed address. If the address is out of range, an error will be generated.

- (ii) A pre-indexed addressing specification:

[Rn] offset of zero

[Rn,<#expression>]{!} offset of <expression> bytes

- (iii) A post-indexed addressing specification:

[Rn],<#expression> offset of <expression> bytes

Rn is an expression evaluating to a valid VY86C060 register number. NOTE if Rn is R15 then the assembler will subtract 8 from the offset value to allow for VY86C060 pipelining.

{!} write-back the base register (set the W bit) if ! is present.

Examples

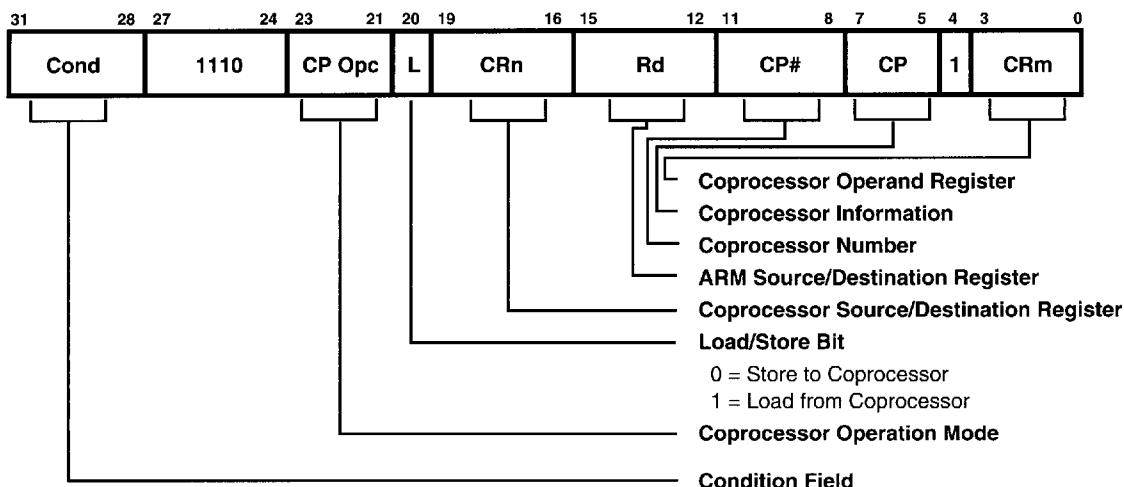

LDC p1, c2, table ; load c2 of coproc 1 from address table,
; using a PC relative address.

STCEQL p2, c3, [R5,#24]! ; conditionally store c3 of coproc 2 into
; an address 24 bytes up from R5, write this
; address back into R5, and use long transfer
; option (probably to store multiple words)

Note that though the address offset is expressed in bytes, the instruction offset field is in words. The assembler will adjust the offset appropriately.

COPROCESSOR REGISTER TRANSFERS (MRC, MCR)

The instruction is only executed if the condition specified in the condition field is true.

This class of instruction is used to communicate information directly between the VY86C060 and a coprocessor. An example of a coprocessor to VY86C060 register transfer (MRC) instruction would be a FIX of a floating point value held in a coprocessor, where the floating point number is converted into a 32-bit integer within the coprocessor, and the result is then transferred to a VY86C060 register. A FLOAT of a 32-bit value in a VY86C060 register into a floating point value within the coprocessor illustrates the use of a VY86C060 register to coprocessor transfer (MCR).

An important use of this instruction is to communicate control information directly from the coprocessor into the VY86C060 CPSR flags. As an example, the result of a comparison of two floating point values within a coprocessor can be moved to the CPSR to control the subsequent flow of execution.

The Coprocessor Fields

The CP# field is used, as for all coprocessor instructions, to specify which coprocessor is being called upon to respond.

The CP Opc, CRn, CP, and CRm fields are used only by the coprocessor, and the interpretation presented here is derived from convention only. Other inter-

pretations are allowed where the coprocessor functionality is incompatible with this one. Conventional interpretation is that the CP Opc and CP fields specify the operation the coprocessor is required to perform, CRn is the coprocessor register that is the source or destination of the transferred information, and CRm is a second coprocessor register which may be involved in some way depending upon the particular operation specified.

Transfers to R15

When a coprocessor register transfer to VY86C060 has R15 as the destination, bits 31, 30, 29, and 28 of the transferred word are copied into the N, Z, C and V flags respectively. The other bits of the transferred word are ignored, and the PC and other CPSR bits are unaffected by the transfer.

Transfers From R15

A coprocessor register transfer from VY86C060 with R15 as the source register will store the PC+12.

Assembler Syntax

<MCRIMRC>{cond} CP#,<expression1>,Rd,CRn,CRm{,<expression2>}

MRC – move from coprocessor to VY86C060 register (L=1).

MCR – move from VY86C060 register to coprocessor (L=0).

{cond} – two character condition mnemonic.

CP# – the unique number of the required coprocessor.

<expression1> – evaluated to a constant and placed in the CP Opc field.

Rd is an expression evaluating to a valid VY86C060 register number.

CRn and CRm are expressions evaluating to a valid coprocessor register number.

<expression2> – where present is evaluated to a constant and placed in the CP field.

Examples

MRC	p2, 5, R3, c5, c6	; request coproc 2 to perform operation 5 ; on c5 and c6, and transfer the (single ; 32-bit word) result back to R3
-----	-------------------	---

MCR	p6, 0, R4, c5, c6	; request coproc 6 to perform operation 0 ; on R4 and place the result in c5
-----	-------------------	---

MRCEQ	p3, 9, R3, c5, c6,	; conditionally request coproc 2 to perform ; operation 7 on c5 and c6, and ; transfer the result back to R3
-------	--------------------	--

UNDEFINED INSTRUCTION

31	28	27	25	24		5	4	3	0
Cond	011		xxxxxxxxxxxxxxxxxxxxxx		1	xxxx			

If the condition specified in the condition field is true, the undefined instruction trap will be taken.

Note that the undefined instruction mechanism involves offering this instruction to any coprocessors that may be present, and all coprocessors must refuse to accept it by driving CPA and CPB HIGH.

Assembler Syntax

At present, the assembler has no mnemonics for generating this instruction. If it is adopted in the future for some specified use, suitable mnemonics will be added to the assembler. Until such time, this instruction shall not be used.

Some instruction codes are not defined but do not cause the Undefined instruction trap to be taken. (For instance, a Multiply instruction with Bit 5 or Bit 6 changed to a 1). These instructions shall not be used, as their action may change in future ARM implementations.

**INSTRUCTION SET EXAMPLES**

The following examples describe ways in which the basic VY86C060 instructions can combine to give efficient code.

These examples are optimized to increase code density therefore reducing storage requirements. Execution time may or may not be reduced.

Using the Conditional Instructions

(1) using conditionals for logical OR

CMP	Rn, #p	; if Rn=p OR Rm=q THEN GOTO
BEQ	Label	; Label
CMP	Rm, #q	
BEQ	Label	

can be replaced by

CMP	Rn, #p	
CMPNE	RM, #q	; if condition is not satisfied try other
		; test
BEQ	Label	

(2) absolute value

TEQ	Rn, #0	; test sign
RSBMI	Rn, Rn, #0	; and two's complement if necessary

(3) multiplication by 4, 5 or 6 (run time)

MOV	Rc, Ra, LSL #2	; multiply by 4
CMP	Rb, #5	; test value
ADDCS	Rc, Rc, Ra	; complete multiply by 5
ADDHI	Rc, Rc, Ra	; complete multiply by 6

(4) combining discrete and range tests

TEQ	Rc, #127	; discrete test
CMPNE	Rc, #"-1"	; range test
MOVLS	Rc, #"."	; IF Rc<=" OR Rc=CHR\$127
		; THEN RC:=". "

(5) division and remainder

; enter with numbers in Ra and Rb

;

	MOV	Rcnt, #1	; bit to control the division
Div1	CMP	Rb, #80000000	; move Rb until greater than Ra
	CMPCC	Rb, Ra	
	MOVCC	Rb, Rb, ASL #1	
	MOVCC	Rcnt, Rcnt, ASL #1	

BCC	Div1	
-----	------	--

MOV	Rc,#0	
-----	-------	--

Div2	CMP	Ra, Rb	; test for possible subtraction
------	-----	--------	---------------------------------

SUBCS	Ra, Ra, Rb	; subtract if ok
-------	------------	------------------

ADDCS	Rc, Rc, Rcnt	; put relevant bit into result
-------	--------------	--------------------------------

MOVS	Rcnt, Rcnt, LSR #1	; shift control bit
------	--------------------	---------------------

MOVNE	Rb, Rb, LSR #1	; halve unless finished
-------	----------------	-------------------------

BNE	Div2	
-----	------	--

;

; divide result in Rc

; remainder in Ra

**Pseudo-Random Binary Sequence Generator**

It is often necessary to generate pseudo-random numbers. The most efficient algorithms are based on shift generators with exclusive-OR feedback rather like a cyclic redundancy check generator. Unfortu-

nately, the sequence of a 32-bit generator needs more than one feedback tap to be maximal length (i.e., $2^{32}-1$ cycles before repetition), so this example uses a 33-bit register with taps at Bits 33 and 20. The basic algorithm is newbit:=bit33

eor bit20, shift left the 33-bit number and put in newbit at the bottom. This operation is performed for all the newbits needed (i.e., 32 bits). The entire operation can be done in 5 S cycles:

```
; enter with seed in Ra (32-bits), Rb (1 bit in Rb 1sb), uses Rc
;
TST      Rb, Rb, LSR #1          ; top bit into carry
MOVS    Rc, Ra, RRX
ADC      Rb, Rb, Rb
EOR      Rc, Rc, Ra, LSL#12     ; (involved!)
EOR      Ra, Rc, Rc, LSR#20     ; (similarly involved!)
;
; new seed in Ra, Rb as before
```

Loading a Word From an Unknown Alignment

; enter with address in Ra (32-bits)
; uses Rb, Rc; result in Rd.
; Note d must be less than c (e.g. 0,1)

```
;
BIC      Rb, Ra, #3          ; get word aligned address
LDMIA   Rb, {Rd, Rc}        ; get 64-bits containing answer
AND      Rb, Ra, #3          ; correction factor in bytes
MOVS    Rb, Rb, LSL #3       ; ...now in bits and test if aligned
MOVNE   Rd, Rd, LSR Rb       ; produce bottom of result word
; (if not aligned)
RSBNE   Rb, Rb, #32         ; get other shift amount
ORRNE   Rd, Rd, Rc, LSL Rb  ; combine two halves to get result
```

Loading a Halfword (LittleEndian)

```
LDR      Ra, [Rb, #2]        ; Get halfword to bits 15:0
MOV      Ra, Ra, LSL #16      ; move to top
MOV      Ra, Ra, LSR #16      ; and back to bottom
; use ASR to get sign extended version
```

Loading a Halfword (BigEndian)

```
LDR      Ra, [Rb, #2]        ; Get halfword to bits 31:16
MOV      Ra, Ra, LSR #16      ; and back to bottom
; use ASR to get sign extended version
```

**Multiplication by Constant Using the Barrel Shifter**(1) Multiplication by 2^n (1, 2, 4, 8, 16, 32..)

MOV Ra, Ra, LSL #n

(2) Multiplication by 2^{n+1} (3, 5, 9, 17..)

ADD Ra, Ra, Ra, LSL #n

(3) Multiplication by 2^{n-1} (3, 7, 15..)

RSB Ra, Ra, Ra, LSL #n

(4) Multiplication by 6

ADD Ra, Ra, Ra, LSL #1 ; multiply by 3

MOV Ra, Ra, LSL #1 ; and then by 2

(5) Multiply by 10 and add in extra number

ADD Ra, Ra, Ra, LSL #2 ; multiply by 5

ADD Ra, Rc, Ra, LSL #1 ; multiply by 2 and add in next digit

(6) General recursive method for $Rb := Ra \cdot C$, where C is a constant:(a) If C even, say $C = 2^n \cdot D$, D odd:

D=1: MOV Rb, Ra, LSL #n

D<1: {Rb := Ra*D}

MOV Rb, Rb, LSL #n

(b) If $C \text{ MOD } 4 = 1$, say $C = 2^n \cdot D + 1$, D odd, n>1:

D=1: ADD Rb, Ra, Ra, LSL #n

D<1: {RB := Ra*D}

ADD Rb, Ra, Rb, LSL #n

(c) If $C \text{ MOD } 4 = 3$, say $C = 2^n \cdot D - 1$, D odd, n>1:

D=1: RSB Rb, Ra, Ra, LSL #n

D<1: {Rb := Ra*D}

RSB Rb, Ra, Rb, LSL #n

This is not quite optimal, but close. An example of its inefficiency is multiply by 45 which is done by:

RSB Rb, Ra, Ra, LSL #2 ; multiply by 3

RSB Rb, Ra, Rb, LSL #2 ; multiply by $4 \cdot 3 - 1 = 11$ ADD Rb, Ra, Rb, LSL #2 ; multiply by $4 \cdot 11 + 1 = 45$

rather than by:

ADD Rb, Ra, Ra, LSL #3 ; multiply by 9

ADD Rb, Rb, Rb, LSL #2 ; multiply by $5 \cdot 9 = 45$

MEMORY INTERFACE

The VY86C060 reads instructions and data from, and writes data to, its main memory via a 32-bit data bus. A separate 32-bit address bus specifies the memory location to be used for the transfer, and the NRW signal gives the direction of transfer. Control signals give additional information about the transfer cycle, and they facilitate the use of DRAM page mode where applicable.

CYCLE TYPES

All memory transfer cycles can be placed in one of four categories:

- (1) Non-sequential cycle. The VY86C060 requests a transfer to or from an address which is unrelated to the address used in the preceding cycle.
- (2) Sequential cycle. The VY86C060 requests a transfer to or from an address which is either the same as the address in the preceding cycle, or is one word after the preceding address.

(3) Internal cycle. The VY86C060 does not require a transfer, as it is performing an internal function and no useful prefetching can be performed at the same time.

(4) Coprocessor register transfer. The VY86C060 wishes to use the data bus to communicate with a coprocessor, but does not require any action by the memory system.

These four classes are distinguishable to the memory system by inspection of the NMREQ and SEQ control lines (see table below). These control lines are generated during phase 1 of the cycle prior to the cycle whose characteristics

they forecast. This pipelining of the control information gives the memory system sufficient time to decide whether or not it can use a page mode access.

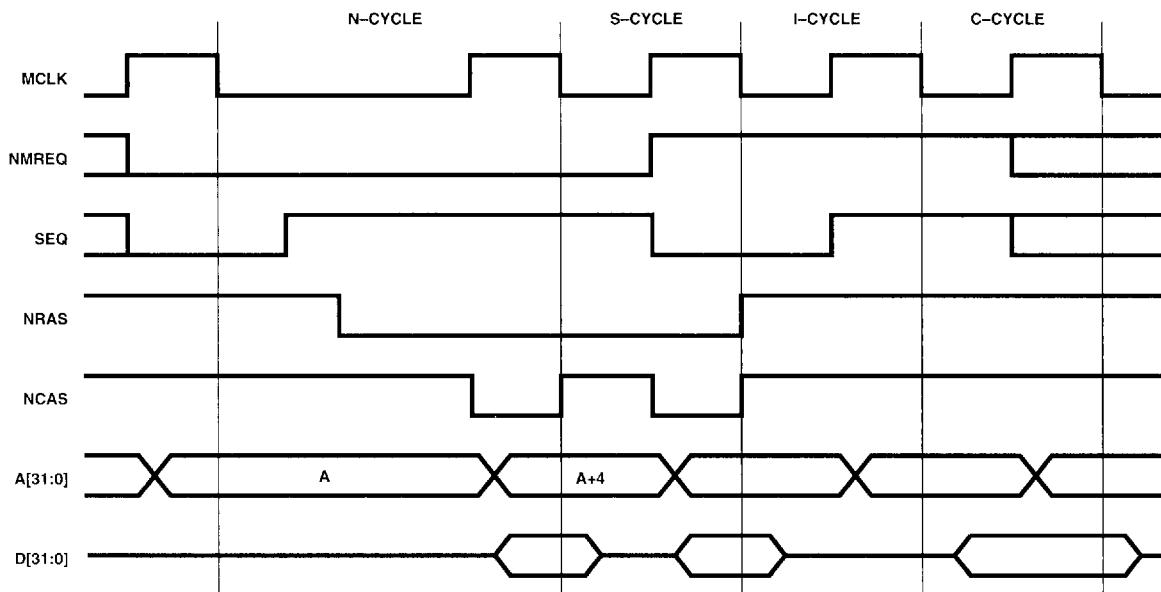

The following diagram shows the pipelining of the control signals, and suggests how the DRAM address strobes (NRAS and NCAS) might be timed to use page mode for S-cycles. Note that the N-cycle is longer than the other cycles. This is to allow for the DRAM precharge and row access time, and is not an VY86C060 requirement.

When an S-cycle follows an N-cycle, the address will always be one word greater than the address used in the N-cycle.

MEMORY CYCLE TYPES

NMREQ	SEQ	Cycle Type	
0	0	Non-Sequential Cycle	(N-cycle)
0	1	Sequential Cycle	(S-cycle)
1	0	Internal Cycle	(I-cycle)
1	1	Coprocessor Register Transfer	(C-cycle)

STRETCHED MEMORY ACCESS TIMING DIAGRAM

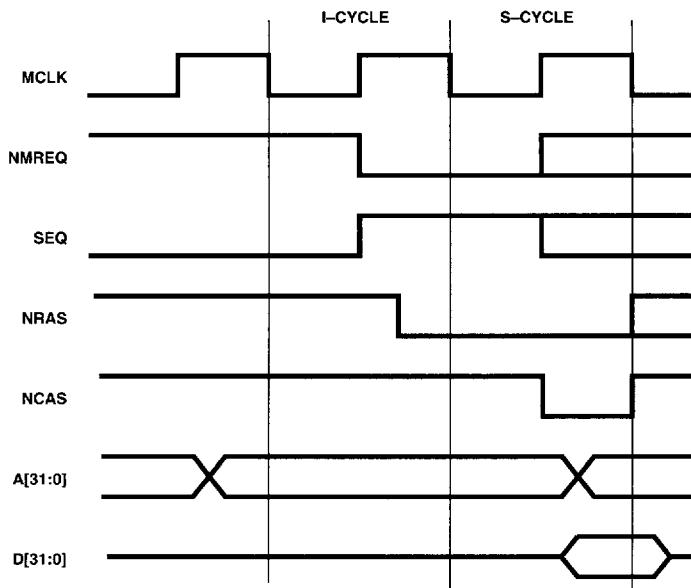

This address (marked "A" in the preceding diagram) should be checked to ensure that it is not the last in the DRAM page before the memory system commits to the S-cycle. If it is at the page end, the S-cycle cannot be performed in page mode and the memory system will have to perform a full access. The processor clock must be stretched to match the full access.

When an S-cycle follows an I- or C-cycle, the address will be the same as that used in the I- or C-cycle. This fact may be used to start the DRAM access during the preceding cycle, enabling the S-cycle to run at page mode speed while performing a full DRAM access.

STANDARD MEMORY ACCESS TIMING DIAGRAM

BYTE ADDRESSING

The processor address bus gives byte addresses, but instructions are always words (where a word is four bytes) and data quantities are usually words. Single data transfers (LDR and STR) can, however, specify that a byte quantity is required. The NBW control line is used to request a byte from the memory system; normally it is HIGH, signifying a request for a word quantity. It goes LOW during phase two of the preceding cycle to request a byte transfer.

When the processor is fetching an instruction from memory, the state of the bottom two address lines A[1:0] is undefined.

When a byte is requested in a read transfer (LDRB), the memory system can safely ignore that the request is for a byte quantity and present the whole word. The VY86C060 will perform the byte extraction internally. Alternatively, the memory system may activate only the addressed byte of the memory in order to save power, or to enable the use of a common decoding system for both read and write cycles.

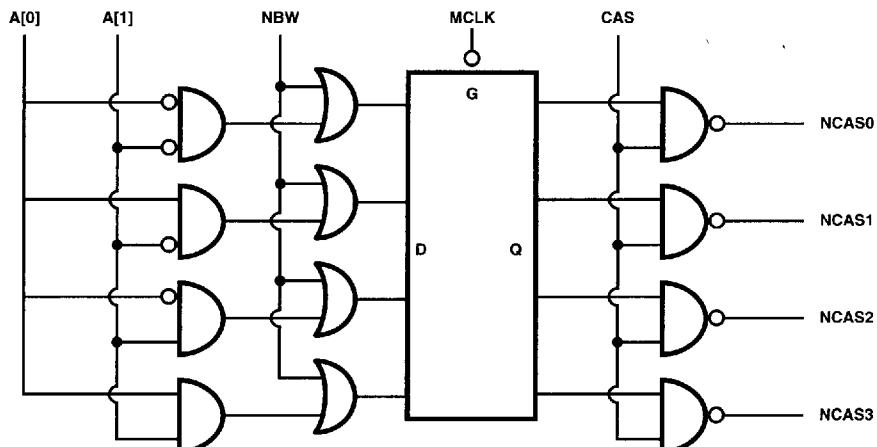

If a byte write is requested (STRB), the VY86C060 will broadcast the byte value across the data bus, presenting it at each byte location within the word. The memory system must decode A[1:0] to enable writing only to the addressed byte.

One method of implementing the byte decode in a DRAM system is to separate the 32-bit wide block of DRAM into four byte wide banks, and generate the column address strobes independently.

When the processor is configured for Little Endian operation, Byte 0 of the memory system should be connected to data lines 7 through 0 (D[7:0]) and strobed by NCAS0. NCAS1 drives the bank connected to data lines 15 through 8, and so on. This approach has the advantage of reducing the load on each column strobe driver, which improves the precision of this time critical signal.

In the Big Endian case Byte 0 of the memory system should be connected to data lines 31 through 24.

BYTE ADDRESSING

ADDRESS TIMING

Normally, during phase 2, the address changes to the value which the memory system should use during the following cycle. This gives maximum time for driving the address to large memory arrays, and for address translation if required. Dynamic memories usually latch the address on chip, and if the latch is timed correctly will work even though the address changes before the access has completed. Static RAMs and ROMs will not work under such circumstances, as they require the address to be stable until after the access has completed. Therefore, for use with static memory the address transition must be delayed until after the end of phase 2 of MCLK. An on-chip address latch, controlled by ALE, allows the address timing to be modified in this way.

In a system with a mix of static and dynamic memories (which for these purposes means a mixture of devices with and without address latches), the use of ALE may change dynamically from one cycle to the next at the discretion of the memory system.

MEMORY MANAGEMENT

The VY86C060 address bus may be processed by an address translation unit before being presented to the memory, and the VY86C060 is capable of running a virtual memory system. The abort input to the processor may be used by the memory manager to inform the

VY86C060 of page faults. Various other signals enable different page protection levels to be supported:

- (i) NRW can be used by the memory manager to protect pages from being written to.
- (ii) NTRANS indicates whether the processor is in User or a privileged mode, and may be used to protect system pages from the user, or to support completely separate mappings for the system and the user.

Address translation may not be necessary on every memory access. This fact may be exploited to reduce power consumption in the memory manager and avoid the translation delay at other times. The occasion when translation is necessary can be deduced by keeping track of the cycle types that the processor uses.

If an N-cycle is matched to a full DRAM access, it will be longer than the minimum processor cycle time. Stretching phase 1 rather than phase 2 of MCLK will give the translation system more time to generate an abort (which must be set up to the end of phase 1).

LOCKED OPERATIONS

The VY86C060 includes a data swap (SWP) instruction that allows the contents of a memory location to be swapped with the contents of a processor register. This instruction is implemented as an uninterruptable pair of

accesses. The first access reads the contents of the memory, and the second writes the register data to the memory. These accesses must be treated as a contiguous operation by the memory controller to prevent another device from changing the affected memory location before the swap is completed. The VY86C060 drives the lock signal HIGH for the duration of the swap operation to warn the memory controller not to give the memory to another device.

STRETCHING ACCESS TIMES

All memory timing is defined by MCLK, and long access times can be accommodated by stretching this clock. It is usual to stretch the LOW period of MCLK, as this allows the memory manager to abort the operation if the access is eventually unsuccessful (abort must be setup to the rising edge of MCLK).

Either MCLK can be stretched before it is applied to the VY86C060, or the NWAIT input can be used together with a free-running MCLK. Taking NWAIT LOW has the same effect as stretching the LOW period of MCLK, and NWAIT must only change when MCLK is LOW.

The VY86C060 does not contain any *dynamic* logic that relies upon regular clocking to maintain its internal state. Therefore, there is no limit upon the maximum period for which MCLK may be stretched, nor is there a limit to how long NWAIT may be held LOW.

COPROCESSOR INTERFACE

The functionality of the VY86C060 instruction set may be extended by the addition of up to 16 external coprocessors. When the coprocessor is not present, instructions intended for it will trap, and suitable software may be installed to emulate its functions. Adding the coprocessor will increase the system performance in a software-compatible way.

INTERFACE SIGNALS

Three dedicated signals control the coprocessor interface, NCPI, CPA and CPB. The CPA and CPB inputs should be driven HIGH unless they are being used for handshaking.

Coprocessor Present/Absent

The VY86C060 takes NCPI LOW whenever it starts to execute a coprocessor (or undefined) instruction. This will not happen if the instruction fails to be executed because of the condition codes. Each coprocessor will have a copy of the instruction, and can inspect the CP# field to see which coprocessor it is for. If the coprocessor's number matches the contents of the CP# field and the coprocessor is capable of executing the instruction, then the coprocessor should drive the CPA (coprocessor absent) line LOW. If no coprocessor is capable of executing the instruction, then CPA and CPB will remain HIGH, and the VY86C060 will take the undefined instruction trap. Otherwise, the VY86C060 observes the CPA line going LOW, and waits until the coprocessor is not busy.

Busy-Waiting

If CPA goes LOW, the VY86C060 will watch the CPB (coprocessor busy) line. Only the coprocessor that is driving CPA LOW is allowed to drive CPB LOW, and it should do so when it is ready to complete the instruction. The VY86C060 will busy-wait while CPB is HIGH, unless an enabled interrupt occurs, in which case it will break off from the coprocessor handshake to process the interrupt. Normally, the VY86C060 will return from processing the interrupt to retry the coprocessor instruction.

When CPB goes LOW, the instruction continues to completion. This will involve data transfers taking place between the

coprocessor and either the VY86C060 or memory, except in the case of coprocessor data operations. Since data operations are performed purely internally to the coprocessor, the VY86C060 treats these instructions as being completed as soon as the coprocessor ceases to be busy. The VY86C060 is then free to execute subsequent instructions while the coprocessor completes its internal operations. Should the coprocessor receive another instruction that requires the same resources, the coprocessor will signal busy until these resources are available.

All three interface signals (NCPI, CPA, and CPB) are sampled by both the VY86C060 and the coprocessor(s) on the rising edge of MCLK. If all three are LOW, the instruction is committed to execution, and if transfers are involved they will start on the next cycle. If NCPI has gone HIGH after being LOW, and before the instruction is committed, the VY86C060 has broken off from the busy-wait state to service an interrupt. The instruction may be restarted later, but other coprocessor instructions may come sooner, and the instruction should be discarded.

Pipeline Following

In order to respond correctly when a coprocessor instruction arises, each coprocessor must have a copy of the instruction. All the VY86C060 instructions are fetched from memory via the main data bus. The coprocessors are also connected to this bus, so they can keep copies of all instructions as they go into the VY86C060 pipeline. The NOPC signal indicates when an instruction fetch is taking place, and MCLK gives the timing of the transfer, so these may be used together to load an instruction pipeline within the coprocessor.

DATA TRANSFER CYCLES

Once the coprocessor has gone not-busy in a data transfer instruction, it must supply or accept data at the VY86C060 bus rate (defined by MCLK). It can deduce the direction of transfer by inspection of the L bit in the instruction, but must only drive the bus when permitted to by DBE being HIGH. The coprocessor is responsible for determining the number of words to be transferred; the VY86C060 will continue to increment the address by one word per

transfer until the coprocessor tells it to stop. The termination condition is indicated by the coprocessor driving CPA and CPB HIGH.

There is no limit to the number of words one coprocessor data transfer can move. However, by convention no coprocessor should allow more than 16 words in one instruction. More than this would lengthen the worst-case interrupt latency of the VY86C060, as the instruction is not interruptible once the transfers have begun. At 16 words, this instruction is comparable with a block transfer of 16 registers, and therefore does not affect the worst-case latency.

REGISTER TRANSFER CYCLE

The coprocessor register transfer cycle is the one case when the VY86C060 requires the data bus without requiring the memory to be active.

The memory system is informed that the bus is required by the VY86C060 taking both NMREQ and SEQ HIGH. When the bus is free, DBE should be taken HIGH to allow the VY86C060 or the coprocessor to drive the bus. The transfer is timed by MCLK.

PRIVILEGED INSTRUCTIONS

The coprocessor may restrict certain instructions for use in privileged modes only. To do this, the coprocessor will have to track the NTRANS signal.

As an example of the use of this facility, consider the case of a floating point coprocessor (FPU) in a multi-tasking system. The operating system could save all the floating point registers on every task switch, but this is inefficient in a typical system where only one or two tasks will use floating point operations. Instead, there could be a privileged instruction that turns the FPU on or off. When a task switch occurs, the operating system can turn the FPU off without saving its registers. If the new task attempts an FPU operation, the FPU will appear to be absent, causing an undefined instruction trap. The operating system will then realize that the new task requires the FPU, so it will re-enable it and save the FPU registers. The task can then use the FPU as normal. If, however, the new task never attempts an FPU operation, the state saving overhead will have been eliminated.

**IDEMPOTENCY**

A consequence of the implementation of the coprocessor interface, with the interruptible busy-wait state, is that all instructions may be interrupted at any point up to the time when the coprocessor goes not-busy. If so interrupted, the instruction will normally be restarted from the beginning after the interrupt has been processed. It is therefore essential that any action taken by the coprocessor before it goes not-busy must be idempotent (i.e., must be repeatable with identical results).

For example, consider a FIX operation in a floating point coprocessor that returns the integer result to an VY86C060 register. The coprocessor must stay busy while it performs the floating point to fixed point conversion. The VY86C060 will expect to receive the integer value on the cycle immediately following that where it goes not-busy. The coprocessor must therefore preserve the original floating point value and not corrupt it during the conversion, because it will be required again if an interrupt arises during the busy period.

The coprocessor data operation class of instruction is not generally subject to idempotency considerations, as the processing activity can take place after the coprocessor goes not-busy. There is no need for the VY86C060 to be held up until the result is generated, because the result is confined to stay within the coprocessor.

UNDEFINED INSTRUCTIONS

Undefined instructions are treated by the VY86C060 as coprocessor instructions. All coprocessors must be absent (i.e., CPA and CPB must be HIGH) when an undefined instruction is presented. The VY86C060 will then take the undefined instruction trap. Note that the coprocessor need only look at Bit 27 of the instruction to differentiate undefined instructions (which all have 0 in Bit 27) from coprocessor instructions (which all have 1 in Bit 27).

INSTRUCTION CYCLE OPERATIONS

In the following tables, NMREQ and SEQ (pipelined up to one cycle ahead of the cycle to which they apply) are shown in the cycle in which they appear, so they predict the address of the next cycle. The address, NBW, NRW, and NOPC (which appear up to half a cycle ahead) are shown in the cycle to which they apply.

BRANCH AND BRANCH WITH LINK

A branch instruction calculates the branch destination in the first cycle, while performing a prefetch from the current PC. This prefetch is done in all cases, since by the time the decision to take the branch has been reached it is already too late to prevent the prefetch.

BRANCH INSTRUCTION CYCLE OPERATIONS

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
1	PC+8	1	0	(PC+8)	0	0	0
2	ALU	1	0	(ALU)	1	0	0
3	ALU+4, ALU+8	1	0	(ALU+4)	1	0	0

(PC is the address of the branch instruction, ALU is an address calculated by the VY86C060, (ALU) are the contents of that address, etc.)

During the second cycle a fetch is performed from the branch destination, and the return address is stored in Register 14 if the link bit is set.

The third cycle performs a fetch from the destination + 4, refilling the instruction pipeline, and if the branch is with link then R14 is modified (4 is subtracted from it) to simplify return from SUB PC,R14,#4 to MOV PC,R14. This makes the STM ..{R14} LDM ..{PC} type of subroutine work correctly.

DATA AND PSR TRANSFER OPERATIONS

A data operation executes in a single datapath cycle except where the shift amount is determined by the contents of a register. A register is read onto the A bus, and a second register or the immediate field onto the B bus. The ALU combines the A bus source and the shifted B bus source according to the operation specified in the instruction, and the result is written to the destination register. (Compares and tests do not produce results, only the ALU status flags are used.) An instruction prefetch occurs at the same time, and the program counter is incremented.

When the shift length is specified by a register, an additional datapath cycle is taken to copy the bottom 8 bits of that register into a holding latch in the barrel shifter. The instruction prefetch will occur during this first cycle, and the operation cycle will be internal (i.e., will not request memory). This internal cycle can be merged with the next sequential access by the memory manager since the address remains stable through both cycles.

The PC may be one or more of the register operands. When it is the destination, external bus activity may be affected. If the result is written to the PC, the contents of the instruction pipeline are invalidated, and the address for the next instruction prefetch is taken from the ALU rather than the address incrementer. The instruction pipeline is refilled before any further execution takes place, and during this time exceptions are locked out.

PSR Transfer operations exhibit the same timing characteristics as the data operations except that the PC is never used as a source or destination register.

MULTIPLY AND MULTIPLY ACCUMULATE

The multiply instructions make use of special hardware that implements a two-bit Booth's algorithm with early termination. During the first cycle, the accumulate register is brought to the ALU, which either transmits it or produces zero (depending on whether the instruction is MLA or MUL) to initialize the destination register. During the same cycle, the multiplier (Rs) is loaded into the Booth's shifter via the A bus.

The datapath then cycles, adding the multiplicand (Rm) to, subtracting it from, or just transmitting, the result register. The multiplicand is shifted in the Nth cycle by 2N or 2N+1 bits, under control of the Booth's logic. The multiplier is shifted right two bits per cycle, and when it is zero, the instruction terminates.

All cycles except the first are internal.

DATA AND PSR TRANSFER CYCLES

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
Normal	1	PC+8 PC+12	1	0	(PC+8)	1	0	0
Dest=pc	1	PC+8	1	0	(PC+8)	0	0	0
	2	ALU	1	0	(ALU)	1	0	0
	3	ALU+4	1	0	(ALU+4)	1	0	0
		ALU+8						
Shift(Rs)	1	PC+8	1	0	(PC+8)	0	1	0
	2	PC+12	1	0	-	1	0	1
		PC+12						
Shift(Rs), dest=pc	1	PC+8	1	0	(PC+8)	0	1	0
	2	PC+12	1	0	-	0	0	1
	3	ALU	1	0	(ALU)	1	0	0
	4	ALU+4	1	0	(ALU+4)	1	0	0
		ALU+8						

MULTIPLY AND MULTIPLY ACCUMULATE CYCLES

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
(Rs)=0,1	1	PC+8	1	0	(PC+8)	0	1	0
	2	PC+12	1	0	-	1	0	1
(Rs)>1	1	PC+8	1	0	(PC+8)	0	1	0
	2	PC+12	1	0	-	0	1	1
	.	PC+12	1	0	-	0	1	1
	m	PC+12	1	0	-	0	1	1
	m+1	PC+12	1	0	-	1	0	1
		PC+12						

(m is the number cycles required by the Booth's algorithm; see the section on Instruction Speeds on page 52.)

**LOAD REGISTER**

The first cycle of a load register instruction performs the address calculation. The data is fetched from memory during the second cycle. The base register modification is also performed during this cycle if required. During the third cycle, the data is transferred to the destination register, and external memory is unused. This third cycle may normally be merged with the following prefetch to form one non-sequential memory cycle.

Either the base or the destination (or both) may be the PC, and the prefetch sequence will be changed if the PC is affected by the instruction.

If the data fetch aborts, the destination modification is prevented. In addition, if the processor is configured for Early Abort, the base register write-back is also prevented.

LOAD REGISTER

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
Normal	1	PC+8	1	0	(PC+8)	0	0	0
	2	ALU	b/w	0	(ALU)	0	1	1
	3	PC+12	1	0	-	1	0	1
		PC+12						
Dest=pc	1	PC+8	1	0	(PC+8)	0	0	0
	2	ALU	b/w	0	PC'	0	1	1
	3	PC+12	1	0	-	0	0	1
	4	PC'	1	0	(PC')	1	0	0
	5	PC'+4	1	0	(PC'+4)	1	0	0
		PC'+8						

STORE REGISTER

The first cycle of a store register is similar to the first cycle of load register. During the second cycle, the base modification is performed, and, at the same time, the data is written to memory. There is no third cycle.

The base write-back is prevented during a Data Abort if the processor is configured for Early Abort. The write-back is not prevented if Late Abort is configured.

STORE REGISTER

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
1	PC+8	1	0	(PC+8)	0	0	0
2	ALU	b/w	1	RD	0	0	1
	PC+12						

**LOAD MULTIPLE REGISTERS**

The first cycle of LDM is used to calculate the address of the first word to be transferred, while performing a prefetch from memory. The second cycle fetches the first word and performs the base modification. During the third cycle, the first word is moved to the appropriate destination register while the second word is fetched from memory. The modified base is moved to the ALU A bus input latch for holding in case it is needed to patch up after an abort. The third cycle is repeated for subsequent fetches until the last data word has been accessed, then the final (internal) cycle moves the last word to its destination register.

The last cycle may be merged with the next instruction prefetch to form a single non-sequential memory cycle.

If an abort occurs, the instruction continues to completion, but all register writing after the abort is prevented. The final cycle is altered to restore the modified base register (which may have been overwritten by the load activity before the abort occurred).

When the PC is in the list of registers to be loaded, and no abort takes place, the current instruction pipeline must be invalidated.

Note that the PC is always the last register to be loaded, so an abort at any point will prevent the PC from being overwritten.

LOAD MULTIPLE REGISTERS

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
1 register	1	PC+8	1	0	(PC+8)	0	0	0

		PC+12						
	n+3	PC'	1	0	(PC')	1	0	0
	n+4	PC'+4	1	0	(PC'+4)	1	0	0
		PC'+8						

STORE MULTIPLE REGISTERS

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
1 register	1	PC+8	1	0	(PC+8)	0	0	0
	2	ALU	1	1	Ra	0	0	1
		PC+12						
n registers (n>1)	1	PC+8	1	0	(PC+8)	0	0	0
	2	ALU	1	1	Ra	1	0	1
	.	ALU+.	1	1	R.	1	0	1
	n	ALU+.	1	1	R.	1	0	1
	n+1	ALU+.	1	1	R.	0	0	1
		PC+12						

**DATA SWAP**

This is similar to the load and store register instructions, but the actual swap takes place in cycles 2 and 3. In the second cycle, the data is fetched from external memory. In the third cycle, the contents of the source register are written out to the external memory.

The data read in cycle 2 is written into the destination register during the fourth cycle.

The LOCK output of the VY86C060 is driven HIGH for the duration of the swap operation (cycles 2 & 3) to indicate that both cycles should be allowed to complete without interruption.

The data swapped may be a byte or word quantity (b/w).

The swap operation may be aborted in either the read or write cycle, and in both cases the destination register will not be affected.

SOFTWARE INTERRUPT AND EXCEPTION ENTRY

Exceptions (and software interrupts) force the PC to a particular value and refill the instruction pipeline from there. During the first cycle, the forced address is constructed, and a mode change may take place. The return address is moved to R14 and the CPSR to SPSR_SVC.

During the second cycle, the return address is modified to facilitate return.

The third cycle is required only to complete the refilling of the instruction pipeline.

DATA SWAP

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	LOCK
1	PC+8	1	0	(PC+8)	0	0	0	0
2	Rn	b/w	0	(Rn)	0	0	1	1
3	Rn	b/w	1	Rm	0	1	1	1
4	PC+12	1	0	—	1	0	1	0
	PC+12							

SOFTWARE INTERRUPT AND EXCEPTION ENTRY

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NTRANS
1	PC+8	1	0	(PC+8)	0	0	0	1
2	Xn	1	0	(Xn)	1	0	0	1
3	Xn+4	1	0	(Xn+4)	1	0	0	1
	Xn+8							

For software interrupt, PC is the address of the SWI instruction. For interrupts and reset, PC is the address of the instruction following the last one to be executed before entering the exception. For prefetch abort, PC is the address of the aborting instruction. For data abort, PC is the address of the instruction following the one that attempted the aborted data transfer. Xn is the appropriate trap address.

**COPROCESSOR DATA OPERATION**

A coprocessor data operation is a request from the VY86C060 for the coprocessor to initiate some action. The action need not be completed for some time, but the coprocessor must commit to doing it before driving CPB LOW.

If the coprocessor can never do the requested task, it should leave CPA and CPB HIGH. If it can do the task, but can not commit immediately, it should drive CPA LOW but leave CPB HIGH until it can commit. VY86C060 will busy-wait until CPB goes LOW.

COPROCESSOR DATA OPERATION

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NCPI	CPA	CPB
ready	1	PC+8 PC+12	1 0	0 -	(PC+8)	0	0	0	0	0	0
not ready	1	PC+8	1	0	(PC+8)	0	1	0	0	0	1
	2	PC+8	1	0	-	0	1	1	0	0	1
	.	PC+8	1	0	-	0	1	1	0	0	1
	n	PC+8 PC+12	1 0	0 -	-	0	0	1	0	0	0

**COPROCESSOR DATA TRANSFER
(FROM MEMORY TO COPROCESSOR)**

Here the coprocessor should commit to the transfer only when it is ready to accept the data. When CPB goes LOW, the VY86C060 will produce addresses and expect the coprocessor to take the data at sequential cycle rates. The coprocessor is responsible for determining the number of words to be transferred, and indicates the last transfer cycle by driving CPA and CPB HIGH.

The VY86C060 spends the first cycle (and any busy-wait cycles) generating the transfer address, and performs the write-back of the address base during the transfer cycles.

COPROCESSOR DATA TRANSFER

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NCPI	CPA	CPB
1 register ready	1	PC+8	1	0	(PC+8)	0	0	0	0	0	0
	2	ALU PC+12	1 0	0 -	(ALU)	0	0	1	1	1	1
1 register not ready	1	PC+8	1	0	(PC+8)	0	1	0	0	0	1

	PC+12										

**COPROCESSOR REGISTER
TRANSFER (LOAD FROM
COPROCESSOR)**

Here the busy-wait cycles are the same as described above, but the transfer is limited to one data word, and the VY86C060 puts the word into the destination register in the third cycle. The third cycle may be merged with the following prefetch cycle into one non-sequential memory cycle as with all VY86C060 register load instructions.

COPROCESSOR REGISTER TRANSFER

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NCPI	CPA	CPB
ready	1	PC+8	1	0	(PC+8)	1	1	0	0	0	0
	2	PC+12	1	0	CPdata	0	1	1	1	1	1
	3	PC+12	1	0	-	1	0	1	1	-	-
not ready	1	PC+8	1	0	(PC+8)	0	1	0	0	0	1
	2	PC+8	1	0	-	0	1	1	0	0	1
	.	PC+8	1	0	-	0	1	1	0	0	1
n	PC+8	1	0	-	1	1	1	0	0	0	0

n+2	PC+12	1	0	-	1	0	1	1	1	-	-
	PC+12										

COPROCESSOR REGISTER TRANSFER (STORE TO COPROCESSOR)

The Store to Coprocessor is similar to the Load from Coprocessor except that the last cycle is omitted.

COPROCESSOR REGISTER TRANSFER

	Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NCPI	CPA	CPB
1 register	1	PC+8	1	0	(PC+8)	1	1	0	0	0	0
	2	PC+12	1	1	Rd	0	0	1	1	1	1
		PC+12									
not ready	1	PC+8	1	0	(PC+8)	0	1	0	0	0	1
	2	PC+8	1	0	—	0	1	1	0	0	1
	.	PC+8	1	0	—	0	1	1	0	0	1
	n	PC+8	1	0	—	1	1	1	0	0	0
	n+1	PC+12	1	1	Rd	0	0	1	1	1	1
		PC+12									

UNDEFINED INSTRUCTIONS AND COPROCESSOR ABSENT

When a coprocessor detects a coprocessor instruction that it cannot perform (this includes all undefined instructions), it must not drive CPA or CPB LOW. If these remain HIGH, the undefined instruction trap will be taken.

UNDEFINED INSTRUCTIONS

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC	NCPI	CPA	CPB
1	PC+8	1	0	(PC+8)	0	1	0	0	1	1
2	PC+8	1	0	—	0	0	0	1	1	1
3	Xn	1	0	(Xn)	1	0	0	1	1	1
4	Xn+4	1	0	(Xn+4)	1	0	0	1	1	1
	Xn+8									

UNEXECUTED INSTRUCTIONS

Any instruction whose condition code is not met will fail to execute. It will add one cycle to the execution time of the code segment in which it is embedded.

UNEXECUTED INSTRUCTIONS

Cycle	Address	NBW	NRW	Data	SEQ	NMREQ	NOPC
1	PC+8	1	0	(PC+8)	1	0	0
	PC+12						

INSTRUCTION SPEEDS

Due to the pipelined architecture of the CPU, instructions overlap considerably. In a typical cycle, one instruction may be using the data path while the next is being decoded, and the one after that is being fetched. For this reason, the adjacent table presents the incremental number of cycles required by an instruction (rather than the total number of cycles for which the instruction uses part of the processor). Elapsed time (in cycles) for a routine may be calculated from these cycle counts.

If the condition is met, the instructions are calculated using:

n as the number of words transferred.

m as the number of cycles required by the multiply algorithm, which is determined by the contents of Rs. Multiplication by any number between $2^{(2m-3)}$ and $2^{(2m-1)} - 1$ inclusive takes $1S + mI$ cycles for $1 < m < 16$. Multiplication by 0 or 1 takes $1S + 1I$ cycles. Multiplication by any number greater than or equal to $2^{(29)}$ takes $1S + 16I$ cycles—this is the maximum number of cycles that any multiply can take.

INSTRUCTION SPEEDS

Data Processing	1 S	+ 1 S for SHIFT(Rs) + 1 S + 1 N if R15 written
MSR/MRS	1 S	
LDR	1 S + 1 N + 1 I	+ 1 S + 1 N if R15 loaded
STR	2 N	
LDM	n S + 1 N + 1 I	+ 1 S + 1 N if R15 loaded
STM	(n-1)S + 2 N	
SWP	1 S + 2 N + 1 I	
B,BL	2 S + 1 N	
SWI,trap	2 S + 1 N	
MUL,MLA	1 S + m I	
CDP	1 S + b I	
LDC,STC	(n-1)S + 2 N + b I	
MRC	1 S + b I + 1 C	
MCR	1 S + (b+1)I + 1 C	

b as the number of cycles spent in the coprocessor busy-wait loop.

If the condition is not met, all instructions take one S cycle.

The cycle types (N, S, I and C) are defined in the Memory Interface Section.

BOUNDARY SCAN

The Boundary Scan Interface conforms to the IEEE Std. 1149.1 - 1990, Standard Test Access Port and Boundary Scan Architecture (please refer to this document for an explanation of the terms used in this section and for a description of the TAP controller states). It supports the following public instructions:

BYPASS
SAMPLE/PRELOAD
EXTEST
INTEST
IDCODE
HI-Z
CLAMP
CLAMPZ

The Boundary Scan Interface consists of five pins on the chip. There are four inputs (INTRST, TMS, TDI and TCK) and one output (TDO). In all the descriptions that follow, TDI and TMS are sampled on the rising edge of TCK and all output transitions on TDO occur following the falling edge of TCK. The diagram below shows the state transitions that occur in the TAP controller.

INSTRUCTION REGISTER

The instruction register is four bits in length.

The fixed value loaded into the instruction register during the *CAPTURE-IR* controller state is 0001.

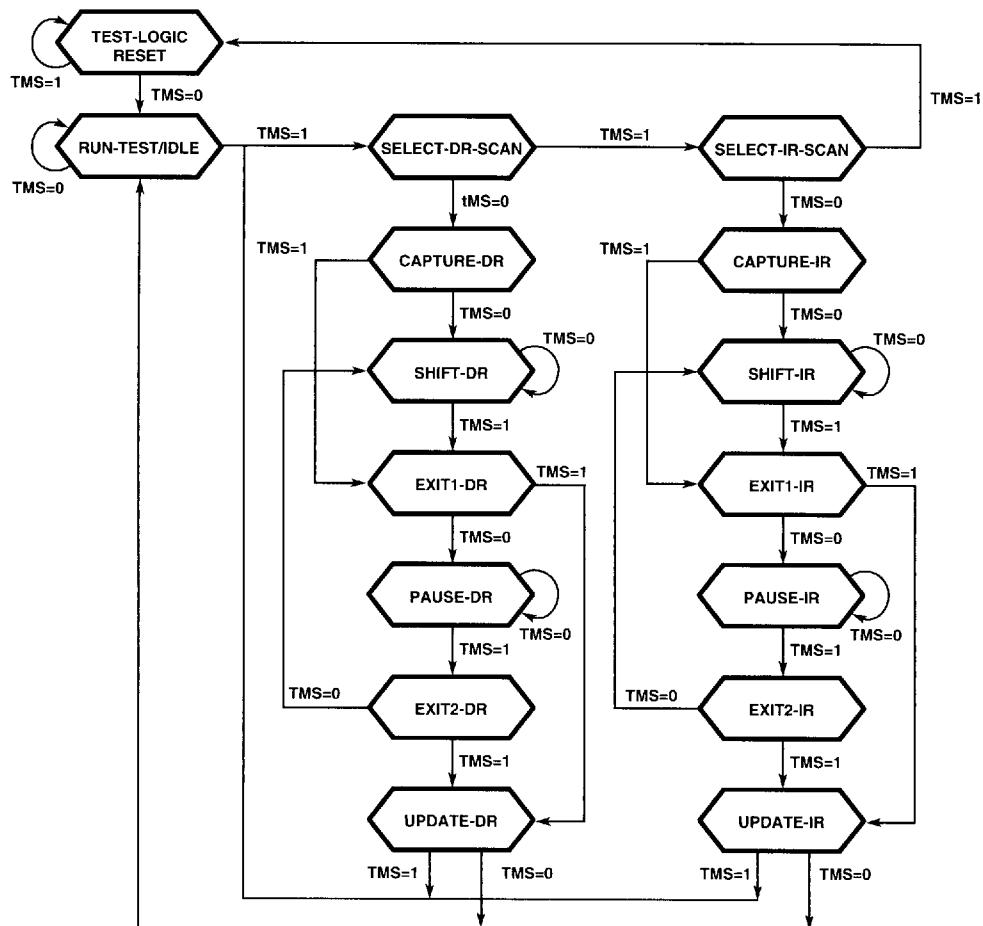

PUBLIC INSTRUCTIONS

The following public instructions are supported:

Instruction	Binary Code
BYPASS	1111
SAMPLE/PRELOAD	0011
EXTEST	0000
INTEST	1100
IDCODE	1110
HI-Z	0111
CLAMP	0101
CLAMPZ	1001

When loading a new instruction, the binary code should be shifted into TDI in order of least-significant bit to most-significant bit.

TAP CONTROLLER STATE TRANSITIONS

**(1) BYPASS (1111)**

The BYPASS instruction connects a 1-bit shift register (the BYPASS register) between TDI and TDO. When the BYPASS instruction is loaded into the instruction register, all the boundary scan cells are placed in their normal (system) mode of operation. This instruction has no effect on the system pins.

In the *CAPTURE-DR* state, a logic '0' is captured by the bypass register. In the *SHIFT-DR* state, test data is shifted into the bypass register via TDI and out via TDO after a delay of one TCK cycle. Note that the first bit shifted out will be a zero. The bypass register is not affected in the *UPDATE-DR* state.

(2) SAMPLE/PRELOAD (0011)

The Boundary Scan (BS) register is placed in test mode by the SAMPLE/PRELOAD instruction.

The SAMPLE/PRELOAD instruction connects the BS register between TDI and TDO.

When the instruction register is loaded with the SAMPLE/PRELOAD instruction, all the boundary scan cells are placed in their normal system mode of operation.

In the *CAPTURE-DR* state, a snapshot of the signals at the boundary scan cells is taken on the rising edge of TCK. Normal system operation is unaffected.

In the *SHIFT-DR* state, the sampled test data is shifted out of the BS register via the TDO pin, while new data is shifted in via the TDI pin to preload the BS register parallel input latch.

In the *UPDATE-DR* state, the preloaded data is transferred into the BS register parallel output latch. Note that this data is not applied to the system logic or system pins while the SAMPLE/PRELOAD instruction is active. This instruction should be used to preload the boundary scan register with known data prior to selecting the INTEST, EXTEST, CLAMP, or CLAMPZ instructions; appropriate guard values to be used for each boundary scan cell are documented in the section entitled Boundary Scan (BS) Register.

(3) EXTEST (0000)

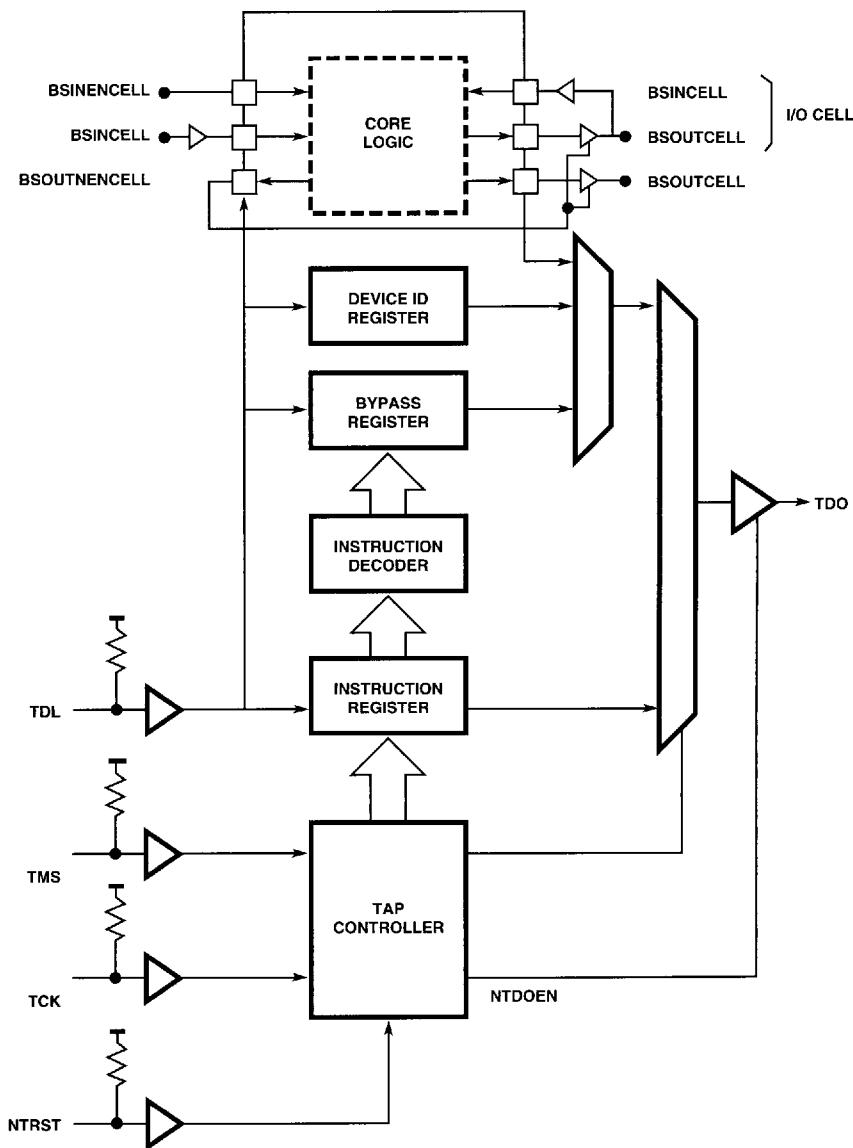

The BS register is placed in test mode by the EXTEST instruction.

The EXTEST instruction connects the BS register between TDI and TDO.

When the instruction register is loaded with the EXTEST instruction, all the boundary scan cells are placed in their test mode of operation.

In the *CAPTURE-DR* state, inputs from the system pins and outputs from the boundary scan output cells to the system pins are captured by the boundary scan cells.

In the *SHIFT-DR* state, the previously captured test data is shifted out of the BS register via the TDO pin, while new test data is shifted in via the TDI pin to

BOUNDARY SCAN BLOCK DIAGRAM

the BS register parallel input latch. In the *UPDATE-DR* state, the new test data is transferred into the BS register parallel output latch. Note that this data is applied immediately to the system logic and system pins.

To ensure that the core logic receives a known, stable set of inputs during *EXTEST*, a set of guarding values must be shifted into some of the boundary scan cells; this guarding pattern is specified in the section entitled Boundary Scan (BS) Register. To ensure that the guarding pattern is in place from the start of the *EXTEST* operation, it should be shifted into the BS register using the SAMPLE/PRELOAD instruction prior to selecting *EXTEST*.

(4) INTEST (1100)

The BS register is placed in test mode by the INTEST instruction.

The INTEST instruction connects the BS register between TDI and TDO.

When the instruction register is loaded with the INTEST instruction, all the boundary scan cells are placed in their test mode of operation.

In the *CAPTURE-DR* state, the inverse of the data supplied to the core logic from input boundary scan cells is captured, while the true value of the data that is output from the core logic to output boundary scan cells is captured.

In the *SHIFT-DR* state, the previously captured test data is shifted out of the BS register via the TDO pin, while new test data is shifted in via the TDI pin to the BS register parallel input latch.

In the *UPDATE-DR* state, the new test data is transferred into the BS register parallel output latch. Note that this data is applied immediately to the system logic and system pins. The first INTEST vector should be clocked into the boundary scan register, using the SAMPLE/ PRELOAD instruction, prior to selecting INTEST to ensure that known data is applied to the system logic.

To ensure that the output pads are placed in a known, stable state during INTEST, a set of guarding values must be shifted into some of the boundary scan cells. This guarding pattern is specified in the section entitled Boundary Scan (BS) Register. To ensure that the guarding pattern is in place from the start of the INTEST operation, it should be shifted into the BS register using the SAMPLE/ PRELOAD instruction prior to selecting INTEST.

Single-step operation is possible using the INTEST instruction.

(5) IDCODE (1110)

The IDCODE instruction connects the device identification register (or ID register) between TDI and TDO. The ID register is a 32-bit register that allows the manufacturer, part number and version of a component to be determined through the TAP.

When the instruction register is loaded with the IDCODE instruction, all the boundary scan cells are placed in their normal (system) mode of operation.

In the *CAPTURE-DR* state, the device identification code is captured by the ID register.

In the *SHIFT-DR* state, the previously captured device identification code is shifted out of the ID register via the TDO pin, while data is shifted in via the TDI pin into the ID register.

In the *UPDATE-DR* state, the ID register is unaffected.

(6) HI-Z (0111)

The HI-Z instruction connects a 1-bit shift register (the BYPASS register) between TDI and TDO.

When the HI-Z instruction is loaded into the instruction register, all outputs are placed in an inactive drive state.

In the *CAPTURE-DR* state, a logic '0' is captured by the bypass register.

In the *SHIFT-DR* state, test data is shifted into the bypass register via TDI and out via TDO after a delay of one TCK cycle. Note that the first bit shifted out will be a zero. The bypass register is not affected in the *UPDATE-DR* state.

(7) CLAMP (0101)

The CLAMP instruction connects a 1-bit shift register (the BYPASS register) between TDI and TDO.

When the CLAMP instruction is loaded into the instruction register, the state of all output signals is defined by the values previously loaded into the Boundary Scan Register. A guarding pattern (specified in the section entitled Boundary Scan (BS) Register) should be preloaded into the Boundary Scan register using the SAMPLE/PRELOAD instruction prior to selecting the CLAMP instruction.

In the *CAPTURE-DR* state, a logic '0' is captured by the bypass register.

In the *SHIFT-DR* state, test data is shifted into the bypass register via TDI and out via TDO after a delay of one TCK cycle. Note that the first bit shifted out will be a zero.

The bypass register is not affected in the *UPDATE-DR* state.

(8) CLAMPZ (1001)

The CLAMPZ instruction connects a 1-bit shift register (the Bypass Register) between TDI and TDO.

When the CLAMPZ instruction is loaded into the instruction register, all outputs are placed in an inactive drive state, but the data supplied to the disabled output drivers is defined by the values previously loaded into the BS register. The purpose of this instruction is to ensure (during production testing), that each output driver can be disabled when its data input is either a '0' or a '1'. A guarding pattern (specified in the section entitled Boundary Scan Register) should be preloaded into the boundary scan register using the SAMPLE/PRELOAD instruction prior to selecting the CLAMPZ instruction.

In the *CAPTURE-DR* state, a logic '0' is captured by the Bypass register.

In the *SHIFT-DR* state, test data is shifted into the Bypass register via TDI and out via TDO after a delay of one TCK cycle. Note that the first bit shifted out will be a zero. The bypass register is not affected in the *UPDATE-DR* state.

TEST DATA REGISTERS

Bypass Register

This is a single-bit register which can be selected as the path between TDI and TDO to allow the device to be bypassed during boundary scan testing.

When the Bypass instruction is the current instruction in the instruction register, serial data is transferred from TDI to TDO in the *SHIFT-DR* state with a delay of one TCK cycle.

There is no parallel output from the bypass register.

A logic '0' is loaded from the parallel input of the bypass register in the *CAPTURE-DR* state.

Device Identification (ID) Code Register

This register is used to read the 32-bit device identification code.

When the IDCODE instruction is current, the ID register is selected as the serial path between TDI and TDO.

There is no parallel output from the ID register.

The following is the format of the 32-bit device identification code that is loaded into the ID register during the *CAPTURE-DR* state:

Bits[31:28]	: Version code
Bits[27:12]	: Part number code
Bits[11:1]	: Manufacturer's code

Boundary Scan (BS) Register

The BS register consists of a serially connected set of cells around the periphery of the device, at the interface between the system (or core) logic and the system input/output pads. This register can be used to isolate the core logic from the pins and then apply tests to the core logic, or conversely to isolate the pins from the core logic and then drive or monitor the system pins.

The BS register is selected as the register to be connected between TDI and TDO only during the SAMPLE/PRELOAD, EXTEST and INTEST instructions. Values in the BS register are used, but are not changed, during the CLAMP and CLAMPZ instructions.

In the normal (system) mode of operation, straight-through connections between the core logic and pins are maintained and normal system operation is unaffected.

During EXTEST or INTEST instructions (i.e., test mode), values can be applied to the core logic or output pins independently of the actual values on the input pins and core logic outputs respectively. Additional boundary scan cells are interposed in the scan chain in order to control the enabling of three-state outputs.

The correspondence between boundary scan cells and system pins, system direction controls and system output enables is shown below. The cells are listed in the order in which they are connected in the boundary scan register, starting with the cell closest to tdi. All outputs are three-state outputs. All boundary scan register cells at input pins can apply tests to the on-chip system logic.

EXTEST/CLAMP guard values specified in the table below should be clocked into the BS register (using the SAMPLE/PRELOAD instruction) before the EXTEST, CLAMP or CLAMPZ instructions are selected to ensure that known data is applied to the system logic during the test. The INTEST guard values shown in the table below should be clocked into the boundary scan register (using the SAMPLE/PRELOAD instruction) before the INTEST instruction is selected to ensure that all outputs are disabled. An asterisk in the guard value columns indicates that any value can be substituted (as the test requires), but ones and zeros should always be placed as shown.

OUTEN0	Output enable active low

**Output Enable Boundary Scan Cells**

The following boundary scan cells control the output drivers of three-state outputs as shown:

No.	Cell Name	Pin	Type	Outputs Controlled
66	NENOUT	-	OUTENO	d[31:0]
67	NCE	-	OUTENO	Nrw, Nbw, lock, Ntrans, Nmreq, seq, Nopc, Ncp1
121	ABE	ABE	INEN1	a[31:0]

In the case of type OUTENO enable cells (NENOUT & NCE), loading a '1' into the cell will disable the associated drivers. In the case of type INEN1 enable cell (ABE), loading a '0' into the cell will disable the associated drivers.

When the SAMPLE/PRELOAD or INTEST instructions are active, the value captured in the NENOUT cell will reflect the state of the NENOUT signal from the core. However, the input of the NCE cell is tied permanently to VSS, so a logic '0' will always be captured by this cell if the SAMPLE/PRELOAD or INTEST instructions are active.

To put all VY86C060 three-state outputs into their high-impedance state, a logic '1' should be clocked into the output enable boundary scan cells NENOUT & NCE, and a logic '0' should be clocked into ABE. Alternatively, the HI-Z instruction can be used.

Single-Step Operation

The VY86C060 is a static design and there is no minimum clock speed. It can therefore be single-stepped while the INTEST instruction is selected. This can be achieved by serializing a parallel stimulus and clocking the resulting serial vectors into the boundary scan register. When the boundary scan register is updated, new test stimuli are applied to the core logic inputs. The effect of these stimuli can then be observed on the core logic outputs by capturing them in the boundary scan register.
